Oligonucleotides and related compounds have been used for decades as affinity ligands for the isolation of DNA-binding proteins involved in transcription, replication, and recombination. The DNA initially used as ligands was nonspecific and derived from calf thymus.

Figure 32 Reversed-phase HPLC separation of lysozyme after selective enrichment from chicken egg white diluted 1 : 9 in water (50 μL injected): (a) without precolumn; (b) with a β-cyclodextrin sulfate precolumn. Nonbinding proteins were eluted from the precolumn by washing with water for 5 min followed by two consecutive injections of 500 μL 20 mM TRIS-HCl buffer, pH 7.5 with 180 mM NaCl with a 2-min interval between injections. The precolumn was then backflushed into the RP system using an isocratic eluent of 35% (v/v) acetonitrile–aqueous 10 mM H_3PO_4. (Reproduced from K. Ishimura et al., *J. Chromatogr. A*, **769**, 213 (1997) by permission of Elsevier Science B.V.)

Modern DNA affinity chromatography uses specific deoxyoligonucleotide sequences that are synthesized and multimerized before attachment to agarose gels[469] or core-shell latex[470] supports. Quantitative zonal DNA affinity chromatography has been used to determine the equilibrium constants of proteins binding nonspecifically to DNA.[471] Jarrett et al. have developed high-performance DNA affinity supports based on silica and reviewed their use,[472] whereas Wheatley et al.[313] have used epoxide-activated HEMA resins and pointed out the advantage of using a high concentration of phosphate buffer when immobilizing double stranded DNA via a 5′-mercaptohexyl spacer. A dihydrazide activation chemistry that could be used to immobilize RNA was developed by Ruhn et al.[309] Yashima et al.[473] prepared a series of nucleic acid mimetic stationary phases by graft polymerizing the vinylic monomers poly(9-vinyladenine), poly(9-adenylethyl methacrylate), and poly(thymylethyl methacrylate) onto porous silica that had been activated with 3-trimethoxysilylpropyl methacrylate. The resulting columns were used for separating nucleosides and nucleotide dimers and oligomers according to an HIC-like mechanism (Figure 33).

Another nonantibody biomacromolecular interaction implemented on solid carriers[474] is the separation of mixtures of RNA and DNA on immobilized histones, basic proteins that bind strongly to DNA. By using a rather concentrated salt gradient, oligonucleotides can be fractionated into partly degraded and intact RNA emerging as two separate peaks at different eluent salt

Figure 33 Separation of oligo(A) (DP = 1–12) and oligo(U) (DP = 1–13) mixtures (terminal 3′- and a mixture of 2′- and 3′-phosphates) on an Si-PTM (poly(thymylethyl methacrylate)) column (125 × 4.6 mm i.d.). Eluents: linear gradient 0–120 min from 1.5 M ammonium acetate (pH 7.0) (100% at 0 min) to 100% water at a flow rate of 0.5 mL min^{-1}; temperature 30 °C. concentrations, followed by a single DNA peak at even higher eluent strength.

5.4.3.11 Screening of Combinatorial Libraries Although a large number of natural ligands have already been developed and evaluated, the quest for new ligands continues as the number of new targets grows rapidly. Libraries of both small molecules and mid-sized peptides have been prepared and screened for activity towards different biomolecules. This approach was primarily used in order to discover new drugs. However, these findings have also afforded new affinants for the preparation of powerful separation media for affinity chromatography of biopolymers.[475,476] Immunochromatographic screening

is based on immobilization of a receptor molecule that is then challenged with a combinatorial library of candidate compounds. The most retained compound is selected for further evaluation. This comprises their preparation in larger scale and immobilization on a support to afford a separation medium for affinity chromatography of the original receptor. Techniques such as introduction of receptors into in vitro biomembrane mimetic structures like liposomes have also started to emerge.[477]

5.4.3.12 Aptamers Combinatorial technologies developed during the 1990s have made it possible to isolate oligonucleotide sequences known as ''aptamers'',[478] which can enter highly specific affinity interactions with a host of target molecules in an antibody-like fashion.[479] These oligonucleotides are produced from random libraries by systematic evolution of ligands by exponential enrichment (SELEX),[480] based on repeated use of affinity chromatography with the immobilized target as ligand followed by enzymatic amplification. Because the PCR technique is used for multiplication of the evolved aptamers, this technique is a highly promising prospect for preparing synthetic biospecific affinity ligands at will. The first application of an aptamer as a ligand in affinity chromatography was published by Romig et al.[481] Using a DNA aptamer selected for its affinity to human L-selectin, they achieved good purification and recovery of a recombinant human L-selectin–Ig fusion protein from Chinese hamster ovary cell-conditioned medium. Aptamers have recently also proven their utility in biosensors,[482] and in the future we should expect to see more applications of the aptamer technology in affinity chromatography.[483,484]

5.4.3.13 Immobilized Metal Ion Affinity Chromatography IMAC[485] is a versatile separation technique for proteins and peptides based on their interaction with certain metal ions sequestered on chelating agents attached to sorbents, and is known under several other prefixes such as metal chelate, metal-ion interaction, and ligand-exchange chromatography. It occupies a position between biospecific affinity and more general techniques of low specificity such as ion exchange. The interaction principle of IMAC is somewhat similar to hydroxyapatite chromatography both in scope and applications. Both techniques are based on metal-ion affinity and are useful for separating and purifying structurally similar proteins.[486–490] Whereas hydroxyapatite is limited to a defined crystalline medium, with few possibilities of altering the interaction pattern, IMAC offers far more degrees of freedom by the choice of support type, chelating group, metal ligand, loading buffers, and eluent conditions. For detailed mechanistic aspects of protein separation by IMAC, the reader is referred to the literature,[425,491–497] and to the references dealing with new ligands and eluents below. The applications are numerous and disparate, and IMAC has been reviewed repeatedly.[498–505] Practical guides are also available in the literature.[505,506] This article will therefore concentrate on recent developments in separation media and studies aimed to gain a better understanding of the separation mechanisms.

The chelating groups present on the IMAC stationary phase are designed to bind metal ions known to interact with amino acid side chain functional groups that are exposed on the surface of proteins. Soft-to-borderline metal ions such as Cu^{2+}, Ni^{2+}, and Zn^{2+} (listed in their general order of decreasing interaction strength with proteins)[507] mainly target histidine, cysteine, and tryptophan, but to some extent also surface-accessible aspartic and glutamic acid residues.[508] The α-amino group of a peptide can also contribute significantly to the retention under certain conditions.[509–512] The binding of a protein is not related to a particular affinity for metal ions, but is dependent on the number and spatial arrangement of these amino acid residues on the protein surface. The use of spacer arms is therefore not as critical in IMAC as in modes where the ligand should reach into the reaction centrum of a protein. Numerous metal-ion chelating groups have been attached to sorbents for use in IMAC, and a critical factor is that the metal ion should be presented in such a way that it is accessible to the protein solutes. The classical chelating group that was introduced by Porath[485] is iminodiacetate (IDA). A chelating group with different properties, also introduced by Porath's group, is tris(carboxymethyl)ethylenediamine (TED).[513] Both moieties are illustrated in Figure 34.

A difference between these two groups is the number of coordination sites occupied by the chelating agent. Whereas IDA is a tridentate chelator, TED is pentacoordinate. This means that fewer coordination sites are available for interaction with the protein when TED is used as chelating group. A consequence is that metal

Figure 34 Two frequently used chelating groups for IMAC sorbents with metal ligands attached: (a) IDA and (b) TED. Both groups have been immobilized through bonding to a support activated by an epoxy group. Note the difference in available coordination sites on the metal ion.

ions sequestered with TED normally have a lower retention. This difference also reflects the kind of metal ions attached to the different chelating groups. Whereas IDA is typically used with divalent transition metal ions of lower coordination number, TED was originally developed for use with the group III ions Al^{3+}, Ga^{3+}, In^{3+}, and Tl^{3+}.[513] Ramadan and Porath have developed a sorbent based on glycinehydroxamate for use with Fe^{3+} as metal ligand,[514] although IDA has remained a popular chelating group for this metal ion. Hochuli et al.[515] introduced nitrilotriacetate (NTA) as a quadridentate alternative to IDA, especially suitable for hexacoordinate metal ions such as Cu^{2+} and Ni^{2+}, leaving two valencies vacant for biopolymer binding. The transition metal ion-mediated retention seen with dye affinity sorbents by Hughes et al.[379] should strictly also be classified as an IMAC-type interaction.

An IDA-functionalized silica for high-performance IMAC was developed and evaluated by El Rassi and Horváth.[516] Wirth et al.[297] developed a new silylation reagent carrying a precursor of the IDA group, which was used to prepare porous and nonporous silica with IDA chelating groups. By using another silylating agent in competition with the IDA silane for available silanols, the density of IDA groups on the surface could be varied, and the IMAC capacity of the porous sorbent leveled off when the coverage with IDA ligand was about 50% of the maximum obtainable. The importance of ligand density control was also demonstrated by Todd et al., in studies of the retention mechanisms of cytochrome *c* histidine variants constructed by site-directed mutagenesis on Cu^{2+}-loaded IDA ligands.[517] Changes in the number of accessible histidines on the protein surface influences the interaction strength, and when multiple interaction points are involved, the binding constant becomes strongly dependent on the availability of metal sites for interaction. The metal ion–ligand stoichiometry is also important; at sufficient chelating ligand density and with less than half the equivalent of metal ions, these become doubly chelated and inaccessible for interaction with the proteins.[517] Further studies on engineered proteins with imidazole added to the eluent have revealed that even a protein with only one surface histidine had an interaction pattern indicating coordination to multiple Cu^{2+} sites on the IMAC support at neutral pH.[518]

Several new chelating moieties have been developed in later years. One of these is a poly(vinylimidazole) with a complexing ability for Cu^{2+}.[519] Metalloprotoporphyrins with different metal centers on silica were found to have strong axial metal–nitrogen interactions with L-histidine, where the metal ion dependence follows the order $Fe^{3+} > Ni^{2+} > Cu^{2+} > Zn^{2+} \approx Cd^{2+}$.[520] These metalloprotoporphyrins phases are also involved in mixed-mode interaction with contributions from $\pi-\pi$ bonding, evident from retention for phenylalanine residues that are normally indifferent in IMAC. An advantage with the protoporphyrin-based chelating groups is the permanent bonding of the metal ion. A silica furnished with β-diketoamine groups by reacting 3-aminopropylated silica with 3-bromopentanedione has been loaded with Cu^{2+} and used for separating α-lactalbumin from milk whey.[521]

Hearn et al. have developed and evaluated a variety of chelating groups. The first in this series was an *O*-phosphoserine (OPS)-modified agarose that showed a stronger chelating capability compared to IDA for Fe^{3+} and Al^{3+} and a selectivity different from the conventional chelating agents.[522] Chelating groups based on 1,4,7-triazacyclononane (tacn) to which the borderline metal ions Cu^{2+}, Ni^{2+}, Zn^{2+}, Co^{2+}, Mn^{2+}, and Cr^{3+} were attached have been found useful for chromatography of several standard protein probes, as well as proteins in partially fractionated human plasma preparations (Figure 35). In connection with these borderline metal ions, the tacn-based sorbents showed a new selectivity toward proteins, compared to previous chelating groups based on IDA, NTA, or OPS.[523] In two recent studies, they make use of 2,6-diaminomethylpyridine[524] and *N*-(2-pyridylmethyl)aminoacetate[525] as chelating moieties in connection with Cu^{2+}. The different selectivities offered by all these new ligands refine IMAC as a separation principle, but in spite of their demonstrated

Figure 35 Elution profile for defibrinylated human serum protein preparation separated on an *im*-Cu^{2+}-tacn-Sepharose CL-6B sorbent using a salt gradient from 20 mM sodium acetate–100 mM NaCl, pH 4.0, to 20 mM sodium acetate–1 M NaCl, pH 4.0, at a flow rate of 0.5 mL min^{-1}. utility, commercial availability is a problem with all the less-common chelating sorbents. Therefore, IDA remains the most widely used sorbent functionality and is available from several sources. Development of an IMAC separation method can be simplified by choosing as the initial system a commercially available chelating support with IDA groups and a strongly interacting metal ion such as Cu^{2+}. If elution becomes difficult, the less retentive metal ions Ni^{2+} and Zn^{2+} should be tested. If these systems do not work, consider alternative chelating groups and metal ions.

As in other interaction chromatographic modes based on polar functional groups, eluent molecules (solvent or buffer substances) will occupy the metal coordination sites in the absence of proteins interacting with these sites. Protein sorption is therefore connected with a metal ion–ligand exchange. It has to be realized that IMAC sorbents are inherently ionic and thus exhibit a conventional ion-exchange capacity,[495] in particular when the immobilized metal ion is a hard Lewis acid.[497] In order to harvest the specific interaction patterns offered by the lone pair Lewis base–Lewis acid ligand exchange mechanism, eluents should therefore always contain salt, and the salt concentration is not uncritical.[526] An implication is that IMAC can be used to separate proteins eluted from ion-exchange columns without intervening desalting, provided that proper adjustments of pH and salt concentration are made before the sample is loaded onto the IMAC column.

There are several ways to control the retention in IMAC and the easiest and most controllable way of eluting the adsorbed proteins from the column is through gradients of decreasing pH,[486,527] or increasing concentration of imidazol.[507] Samples are normally loaded from neutral or weakly alkaline buffers. The pH gradients operate by changing the degree of ionization of histidine and other interacting groups on the protein surface, whereas the imidazole gradients act by competing for the metal chelating binding sites. Gradient pH elution works with most retained proteins, unless the binding is too strong, in which case a less-retentive chelating group could be considered. Phosphorylated amino acids, phosphopeptides and phosphoproteins interacting with Fe^{3+}–IDA are exceptions,[528] where elution is accomplished by increasing the buffer pH or the phosphate concentration,[529] or by using phosphoserine or a displacing metal ion such as Mg^{2+}.[530] This specific type of interaction is particularly valuable for trapping low concentrations of phosphoproteins for MS analysis.[531] Displacement of proteins from Cu^{2+} complexes can take place by substituting ammonium for the loading buffer salt cation[486] (which should obviously not be ammonium ion or an amine such as TRIS). Imidazole is also a widely used eluent with Ni^{2+} and Zn^{2+} IDA chelates, where its advantage over pH gradient elution is that the metal ions remain on the sorbent during elution.[507] Elution by decreasing pH and increasing imidazole gradients produce similar elution pattern, as shown by Yip et al.,[532] who investigated the interactions of a large number of synthetic peptides (up to 42 amino acids long) on a polymeric high-performance IMAC sorbent with IDA groups and Cu^{2+}, Ni^{2+}, and Zn^{2+} as metal ions. A third way of eluting is to add a chelating agent such as ethylenediamine tetraacetic acid (EDTA) to the eluent. This procedure will also release the metal ion from the immobilized chelate, in which case the column must be reloaded before next use. However, leakage of metal ions does take place with most eluents, in particular if compounds having a strong interaction with the metal ligands such as glycine or primary amines are present in the eluent,[507] so a prudent practice is to always reload between runs, unless a very stable chelate is used in the column. A reloading cycle typically comprises stripping off remaining metal ions with a complexing agent such as EDTA at neutral pH, followed by reloading of metal ions onto the chelating groups on the sorbent.

The IMAC technique has become part of a unique biotechnological purification scheme through a technology known as ''His-tagging''.[533,534] This tagging takes place by extending the nucleotide sequence coding for a protein to be produced by recombinant technology by the codons for a chelating peptide, generating the gene for a chimeric metal-chelating peptide–protein that can be cloned and expressed. The metal-chelating peptide fusion handle is thereafter used for IMAC purification on an Ni^{2+}–NTA resin, whereafter it is removed by chemical or enzymatic cleavage so that the protein regains its natural amino acid sequence. Inclusion of a terminal sequence consisting of six histidines is most common,[534] although fewer histidines in controlled sequences provide for weaker interactions and possibilities of using softer elution conditions.[535–537] A technique related to His-tagging has recently been used to bestow IMAC retention to DNA produced in a PCR scheme.[538] The His-tag IMAC interaction has also been used for oriented immobilization of antibodies for immunoaffinity chromatography.[539] A recent paper furthermore describes the use of a His-tag in combination with anti-His-tag antibodies for a tandem affinity (IMAC and immunoaffinity) separation of His-tagged proteins.[540] An example of an IMAC separation based on his-tagging is shown in Figure 36.

Metal ion affinity can be used for reversible immobilization of native proteins to affinity-sorbent surfaces, as shown by the preparation of an affinity phase with variable and controlled amounts of Con A using Cu^{II} chelated to IDA porous silica.[541] Although a wide range of eluent conditions could be used without loss of the

Figure 36 Anti-His-tag immunoaffinity chromatography of a His-tagged mini-antibody (a homodimerized single-chain Fv fragment with a His_6-tag fused to the C-terminus via a linker; sequence scFv-GGSGGAPGHHHHHH) after preliminary purification by IMAC. The affinity stationary phase contains an anti-His-tag antibody (3D5) immobilized onto an Affi-Hz hydrazide support. Biochem.*, **259**, 60 (1998) by permission of Academic Press.)

lectin, its detachment could still rapidly be accomplished by eluting with low pH or EDTA. The existence of dual functionalities produced a mixed retention mechanism, characteristic of both IMAC and lectin affinity chromatography.

A different kind of metal interaction chromatography takes place on organomercurial resins, whereupon nucleosomes containing transcriptionally active chromatin unfold and uncover the sulfhydryl groups of a histone, enabling its interaction with reagents having affinity for sulfhydryl groups.[542]

5.4.4 Salt-promoted/Thiophilic Adsorption Chromatography

Porath et al.[543] discovered in 1985 that thioether–sulfone gels, prepared by activation of agarose by divinylsulfone and coupling of 2-mercaptoethanol (Figure 37), have an enhanced affinity towards certain human serum proteins, in particular Igs. The retention appeared to be unique and quite different from hydrophobic interaction, and it works for all three major classes of Igs and their subclasses. This particularly mild technique, which was termed

Figure 37 Thioether–sulfone functional group of Porath's original thiophilic gel.[543]

thiophilic adsorption chromatography (TAC), provides for efficient recovery of pure Igs at neutral pH from complex biological matrices.[544] Synthesis of surface-functionalized rigid material for high-performance TAC has also been described;[147,545,546] TAC has also been carried out in the membrane format.[547]

The TAC method is a typical on–off affinity technique. The sample is loaded onto the column in a 10–100 mM buffer at neutral pH, to which a 0.5–1 M solution of a cosmotropic salt, typically sodium, potassium, or ammonium sulfate, has been added. The buffer type does not appear to have any significant influence on the result. Examples of buffers are phosphate, borate, and zwitterionic aminosulfonic acids. Although the target is retained, the nonadsorbed molecules are washed away by the running salt-containing buffer. Elution occurs once the mobile phase is changed in a single step to the buffer solution only, or by a gradient of decreasing concentration of the adsorption-promoting salt.[548] Figure 38 shows a separation of mouse Ig subclasses.[147] This facile attachment and detachment of Igs furthermore allows TAC media to be used as immobilization sorbents in flow immunoassays.[549–552]

Apart from Ig purification, thiophilic adsorption sorbents have also found use as stationary phases for the separation of amylases[553,554] and for purification of allergens from horse sweat.[555] Experiments by Noel et al.[556] have shown that the presence of a thioether moiety is not essential to promote adsorption of Igs by thiophilic stationary phases. Instead, their ability to retain Igs appears to be connected

Figure 38 Elution profile of mouse ascitic fluid containing IgG3 (1), pure IgG1 (2), and their mixture (3) on a thiophilic column (125 × 4 mm i.d.) based on a DEAE–dextran-coated silica. (Reproduced from A. Serres et al., *J. Chromatogr. A*, **711**, 156 (1995) by permission of Elsevier Science B.V.)

with the divinylsulfone activation/cross-linking, making "thiophilic" a somewhat inappropriate name for what is in reality a salt-promoted retention effected by varying concentrations of cosmotropic anions (compare HIC). This observation was subsequently verified by others.[272,557,558]

Several new separation media have recently been synthesized, partly as a result of these findings, by attaching propylamine, allylamine, aminoacetonitrile, 2-aminocrotonitrile, 1,2-diamino-maleonitrile and tricyanoaminopropene to 1,4-butanediol diglycidyl ether and divinyl sulfone activated agarose.[559] In this study it was found that the nature of the spacer arm and cyano-substitution in the ligand influenced the affinity for proteins, and that the agarose activated by divinyl sulfone and reacted with tricyanoaminopropene had the highest adsorption for proteins. This ligand was consequently studied further and was found to have unique adsorption properties for proteins with binding being both dependent and independent of promotion by salt, which led to a proposed electron donor–acceptor adsorption mechanism for the observed interactions.[560] Results by Schwarz et al.[546] and Scholz et al.[557,561] show that heterocyclic ligands may be a viable route to selective sorption of Igs from solutions of low salt concentration. It thus appears that the salt-promoted "thiophilic" adsorption principle is not limited to antibodies, but is of a more general nature.

5.4.5 Multidimensional Affinity Chromatography

The high specificity of affinity chromatography, the relative insensitivity to variations in buffer conditions during the binding step, and the highly specific elution schemes make it possible to combine several affinity chemistries in a single separation. For instance, immobilized anti-HSA and protein A were bound to different silica columns coupled in tandem for capturing albumin and IgG from human serum.[562] Wheat germ agglutinin was used to separate sialoglycoproteins and the individual fractions were subjected to IMAC on a Cu^{2+}-loaded IDA silica.[563] A technique termed cascade-mode multiaffinity chromatography has been developed on traditional soft media to exploit the group-resolving power of affinity chromatography.[564] A column train consisting of (a) a Zn^{2+}–TDA IMAC gel, (b) a thiophilic gel, (c) Zn^{2+} chelated to dipicolylamine (DPA) agarose, (d) a hexyl-thioether agarose, and (e) Ni^{2+}–DPA agarose was capable of trapping >99% of the protein in human serum from the same high salt-containing buffer. Following adsorption, each column was connected to other column types for further separation in a minimized number of operations, so that essentially complete fractionation of serum protein was accomplished with high resolution, recovery, and capacity.

5.5 Ion-exchange Chromatography and Related Techniques

Ionic separation materials have been used in biopolymer separations for more than half a century and IEC (or electrostatic interaction chromatography as it should probably be called) has become one of the most widely used techniques for analytical and preparative separation of proteins.[565] It is also applicable to other charged biomacromolecules. The popularity comes from an excellent separation power, good possibilities of tuning the separations by selecting columns containing a variety of commercially available stationary phases with many different ionic functional groups, a soft interaction mode due to the buffered fully aqueous salt gradients typically used for elution, and a high sample capacity. The IEC technique is therefore often used in the early preparation stages where overloading is more likely to occur. Ion exchange is also often part of mixed-mode techniques (see below), where an additional separation dimension is allowed to contribute to the overall separation. Books dedicated to IEC are not abundant in the recent literature,[566] but chapters on IEC are found in most books on HPLC of biological macromolecules.[565,567–570]

The separation principle is based on electrostatic interactions between fixed ionic charges on the stationary phase and oppositely charged functional groups on the surface of the solute molecules. The retention is controlled by the charges of the stationary phase and the solute, and the ionic strength of the medium. Ions that are electrostatically attached to the ion-exchange groups are referred to as counterions, whereas ions of the same charge sign as the ion exchanger are termed co-ions. The fixed charges of the ion-exchange material can be either anionic, in which case the material is a cation exchanger, or cationic, giving the properties of an anion exchanger. Ion-exchange materials are also classified as weak or strong, depending on whether the ionic functional group has a dissociation or protonation equilibrium in the operational pH range, or maintains its charge when pH is changed. A compilation of the most common ion-exchange sorbent functionalities used for biomacromolecule separations is presented in Table 6.

Due to adjacent group effects and changes in solvation and cross-linking, there is a wide span in apparent pK values of individual functional groups in weak ion exchangers, manifested in shallow titration curves, often with steps. The pK values in Table 6 are therefore only approximate. This functional group heterogeneity affects weak anion-exchange materials in particular, where for instance materials based on cross-linked PEI[150] contain a mixture of primary, secondary, and tertiary amine groups, whereas DEAE materials contain tandem functionalities where one DEAE group is reacted on top of another

Table 6 Typical functionalities and key properties of the most common ion-exchange sorbent types for biopolymer chromatography

Ion exchanger type	Functional group	Representative functional group[a]	Designation[b]	p*K*[c]	pH range[d]
Weak cation exchanger (WCX)	Carboxyl	Support−COO^-	CM	≈5	6–13
Strong cation exchanger (SCX)	Sulfoalkyl	Support−$CONH-C(CH3)_2CH_2SO_3^-$	S	<1	2–13
Weak anion exchanger (WAX)	Diethylaminoethyl	Support−$CONH-(CH_2)_2N(C_2H_5)_2H^+ X^-$	DEAE	≈11	2–10
Strong anion exchanger (SAX)	Quaternary ammonium	Support−$CONH-(CH_2)_2N(CH_3)_3^+$	Q	>13	2–12

[a] The linkages are those often used on polysaccharide materials. Functional groups attached to synthetic polymers may be slightly different.
[b] Common abbreviation used by column manufacturers to identify the functional group.
[c] p*K* values of polymer-bound ionic groups are approximate and dependent on the functional group structure, the polymer matrix, steric factors, ionic strength, etc. Titration curves are typically shallow, which means that the net surface charge cannot be calculated directly from the p*K*.
[d] Operational pH range determined by the ionization equilibrium of the ionic/ionogenic group. Other factors may limit this range.

in a quaternizing reaction, leading to a relatively wide distribution in p*K*.[565] The titration curve of a weak anion exchange resin can thus take the shape shown in Figure 39.

From these curves, it is also apparent that the charge density of a weak anion exchanger is substantially influenced by the ionic strength of the medium, which typically changes during gradient elution. Optimization of separations on weak ion exchangers can therefore be complicated and strong ion exchangers (the S or Q types) are often preferred because they provide a more predictable retention through their lack of disturbing dissociation and protonation equilibria.[572] The retention at varying pH is thereby governed only by changes in charge of the solute. Another parameter affecting the retention is the charge density of the ion-exchange material, which is one of the factors controlling the selectivity.[149,573]

The versatility stems from the fact that practically all biomacromolecules, with asialic polysaccharides being the notable exception, have functional groups that are

Figure 39 Ionization of a pellicular PEI weak anion exchanger as a function of pH and ionic strength. The curves are obtained by titrating with 0.1 M HCl in both distilled water and 1.0 M NaCl. (Reproduced from W. Kopaciewicz et al., *J. Chromatogr.*, **266**, 14 (1983) by permission of Elsevier Science B.V.)

charged, or can become charged through dissociation or protonation equilibria within the normal operating pH range of biopolymer separations. This sensitivity to changes in pH provides a key to tuning the selectivity in IEC and also provides for different IEC separation dimensions for the same biomacromolecule. A protein is characterized by its p*I*, where its net charge is equal to zero. The dissociation of acidic groups and protonation of basic groups on the protein surface produces a negative charge when the pH is increased above the p*I* value, and conversely results in a positive charge when the pH is lower than p*I*. A protein can therefore be separated on both anion- and cation-exchange columns, provided its p*I* is not extreme and the pH stability is sufficient. In principle, a protein should not have retention, neither on an anion exchanger nor on a cation exchanger, at its exact p*I*,[574] as illustrated in Figure 40.

The steepness of the titration curve is quite different among proteins, as is the p*I*, and even subtle differences, such as the substitution or deamidation of a single-surface amino acid, can cause a sufficient difference in charge properties to allow separation by IEC.[575] The charge properties are mediated by acidic and basic lateral groups of the protein, as listed in Table 7.

Basic proteins thus have a high p*I* and an excess of basic groups. Histones and chicken egg white lysozyme (p*I* 11.3–11.6) are among the most strongly basic proteins. Acidic proteins have an excess of acidic groups and thus low p*I*s. For instance, pepsin has a p*I* of close to 1. Most proteins have p*I*s lower than 7 and are therefore negatively charged at neutral pH. Carboxylate groups from sialic acid in sialoglycoproteins, γ-carboxyglutamate in blood coagulation factors, and phosphoserine in phosphoproteins also contribute to the charge of such proteins.[565] The charge properties of a protein are also dependent on the conformation. The addition of structure-altering agents such as solvents, detergents, water-soluble polymers, and chaotropic and cosmotropic ions can therefore selectively alter the retention of a protein in IEC.[565] Very rough estimates of the p*I* of a

Figure 40 Diagram of (a) the net charge and (b) retention factor dependency on the mobile phase pH in relation to the p*I* of a protein, assuming that proteins are retained based on their net charge only. (Adapted from G. Choudhary, C. Horváth, *Methods Enzymol.*, **270**, 55 (1996) by permission of Academic Press.)

protein can be calculated[576] from amino acid side-chain dissociation and protonation constants if the primary structure is known. Without knowledge of the p*I*, a sound approach to IEC separation of an unknown protein would be to load the protein from a slightly basic solution onto an anion exchanger and use a salt gradient at this pH.

As just mentioned, a noncharged molecule should not interact with an ion exchanger through electrostatic mechanisms. However in practice many proteins do interact significantly with ion-exchange sorbents at their p*I*, causing a retention that is commonly attributed to an inhomogeneous charge distribution on the molecule surface.[571] A biomacromolecular solute with zero net charge can thus have charge patches of either sign, providing ''contact surfaces'' with the ion exchange material. For this reason it is often postulated in the literature that proteins have preferred orientations in their interactions with charged surfaces. Because ionic interactions act over relatively long ranges and through gradients that extend from the surface, this heterogeneous charge distribution can enable the molecule to get attached to both anion- and cation-exchange resins at its p*I*, using different orientations. The steepness of the titration curve appears to be involved in determining the extent of electrostatic interaction at the solute p*I*.[577]

A central parameter in the discussion of retention in IEC is the Z number,[571] which is used to visualize the number of charged sites involved in the interaction between the solute and the ionic stationary phase. The Z number is determined as the steepness of the relationship between $\log k'$ and the logarithm of the molality of the eluent obtained from a series of isocratic elution experiments. Because Z numbers usually assume rather high values, high resolutions can be obtained in IEC as a result of the reasons discussed above for hydrophobic separation techniques.

In its most simplistic form, the force between the charges on the sorbent involved in the interaction Z_s, and the corresponding charges on a biopolymer solute Z_p, separated from each other by the distance r, follows Coulomb's law (Equation 25),

$$F = \frac{Z_s Z_p}{Dr^2} \tag{25}$$

where D is the dielectric constant of the solvent. Ionic interaction forces are therefore weaker in water with

Table 7 Charged amino acid lateral groups and some other charge-promoting groups in proteins[565]

Group	Structure	pK_a		Occurrence in proteins (%)
		Proteins	Free amino acids	
Arginine	Guanidino	12.0	12.5	5.7
Aspartic acid	Carboxylate	3.9–4.0	3.7	5.3
Cysteine	Thiol	9.0–9.5	10.6	1.73
Glutamic acid	Carboxylate	4.3–4.5	4.3	6.2
Histidine	Imidazole	6.0–7.0	6.1	2.2
Lysine	ε-Amino	10.4–11.1	10.7	5.7
Tyrosine	Phenol	10.0–10.3	10.4	3.2
α-Amino	Amino	6.8–8.0	–	–
α-Carboxyl	Carboxylate	3.5–4.3	–	–

a dielectric constant close to 80, compared to typical water-miscible organic solvents used as eluents, whose dielectric constants are in the range 20–30. Concerning the retention mechanism for IEC when operated in fully aqueous solution, there are two conflicting views. The traditional retention model, which has its roots in the 1955 Boardman and Partridge's paper,[574] is based on the conception that a stoichiometric exchange of counterions takes place on the sorbent when the protein docks at the surface. This model, referred to as the KRFR model, was formalized and verified on experimental data over a limited concentration range by Kopaciewicz et al.[571,578] In a large number of subsequent works by many authors, this empirical model has served as a tool for modeling the retention within the eluent concentration and sorbent charge density ranges normally used in IEC, and has provided data that are meaningful in the context of pI and charge densities on protein surfaces. The KRFR model is based on the linear relationship that appears to exist between $\log k'$ and $-\log I$, where each protein has a characteristic slope, Z, interpreted as the number of ionic groups on the protein that are involved in the interaction process. The Z numbers are therefore dependent on the charge status of the protein and hence on the pH. The KRFR model has later been expanded to include the shorter range van der Waals interactions,[579] in order to account for retention observed on ion-exchange materials at high salt concentrations due to the hydrophobic effect.

A rather different view on the retention process was presented by Ståhlberg et al.,[573] who applied ideas from particle interaction in colloidal science to explain the retention in terms of long-range interactions based on averaging the charge of the protein and treating the sorbent surface as a charged flat slab (the SJH model). In terms of predicting retention, the main difference is that the SJH model forecasts $\log k'$ to be a linear function of the logarithm of the inverse square root of the ionic strength I, instead of the logarithm of the inverse first power of I, as predicted by the KRFR model. The first version of the SJH model could account only for the long-range electrostatic interactions. Subsequent refinements have also taken van der Waals interactions[580] and charge regulation theory[577] into account. The current model can couple the slope of the titration curves of proteins at the pI to retention at zero net charge, which can take place even on sorbents with the same net charge as the protein[572,581] (Figure 41). A mechanistic treatment of the KRFR model (the RUL model)[582] has been introduced, taking into account protein size and net charge and adopting a simplified form of the sphere–plate concept, on which the SJH model is based. Similar to the KRFR model, the RUL model explains $\log k'$ as being a linear function of $\log I$. However, according to Ståhlberg's recent review of retention models for IEC,[583] the RUL

Figure 41 Gradient elution of β-lactoglobulin (Lg) A and B (p$I \approx 5.1$ and 5.2, respectively) near their pIs with (a) anion-exchange chromatography and (b) cation-exchange chromatography. The gels (see legend in Figure) were packed in glass columns (150 × 8 mm i.d.) and eluted with a gradient from 30 to 500 mM NaCl in 10 mM acetate buffer, pH 5.2, at a temperature of 25 °C and a flow rate of 1 mL min^{-1}. The gradient rate was chosen to accomplish baseline separation of LgA and LgB. (Reproduced from S. Yamamoto, T. Ishihara, *J. Chromatogr. A*, **852**, 33 (1999) by permission of Elsevier Science B.V.)

model is applicable only when the distances between the protein and the ionic surface are long. The SJH model is supported by studies of ionic retention on SEC materials with very low charge density,[190] a situation that cannot be treated by the KRFR model and its extensions. Yet at present the tradition model continues to prevail,[584,585] and as pointed out by Roth et al.,[582] the experimental data that were correlated on a log versus log square root plot to verify the SJH model can also be fitted to the KRFR model with a log–log plot.

Among the more interesting developments in IEC during the 1990s are tentacle gels and perfusion media. The

latter behave similar to other IEC resins, except that the mass transfer is improved, and are treated in a separation section of this text. Tentacle ion-exchange materials are produced by surface-initiated graft polymerization of linear oligomers combs, comprised of monomers with lateral ionic groups comprising 5–50 charged moieties per ligand unit, amounting to a length of up to ≈10 nm in the fully extended state.[163] These tentacle gels were found to absorb proteins to a degree which by far exceeds a monolayer coverage, and exhibit up to four times higher protein sorption capacity compared to corresponding surface functionalized materials.[88] A seemingly rational explanation for this high capacity is that the protein must be adsorbed in multilayers or dissolved within the polymer layer.[88] However, this cannot be contemplated in view of more recent theories of protein interaction with ion-exchange sorbents founded in colloid science, as discussed above. Recent experiments by Ratnayake and Regnier,[586] based on a series of tentacle-grafted cation-exchange sorbents synthesized with varying ligand density and tentacle length, have shown that the retention mechanism of tentacle ion exchangers is similar to surface functionalized materials. It was also concluded that some cross-linking exists in the tentacle layers prepared by free radical grafting, so that not all the polyacrylate chains are in fact tentacles. Another investigation has linked the higher capacity of tentacle gels to the increased flexibility of the ionic functional groups.[587]

Hearn's group has also conducted several studies on tentacle ion exchangers. When comparing tentacle type and conventional polymeric surface functionalized anion-exchange material,[588] they found that the retention followed a $\log k'$ versus $\log I$ relationship, and that some proteins were not, or only weakly, retained in spite of an eluent pH that was several units above the protein p*I*s. There were also significant differences between a silica-based and a polymer-based tentacle material used in these tests. In a study of salt and pH effects on band broadening,[589] the two types of tentacle materials tested behaved quite differently. These differences were attributed to a dynamic interplay between the tentacle ligands and the protein solutes. On studying the adsorption of different proteins in batch experiments with a silica-based tentacle cation exchanger,[590] it was found that most tested proteins were absorbed according to an ion-exchange mechanism. Lysozyme and insulin were the only exceptions, for which the sorption capacity increased with the concentration of salt. This odd retention behavior was interpreted as a hydrophobic effect. In a comparative study of two grafted strong cation-exchange materials[584] – a tentacle-type material and a polysulfoethyl aspartamide-coated silica – the Z numbers for the tested proteins were found to be higher for the tentacle gel, indicating that the flexible interaction layers interact with proteins through larger contact areas. The hydrophobic contribution to the retention also appeared to be higher on the polysulfoethyl aspartamide material. In a study of the bandwidth characteristics of the same sorbents at different temperatures,[591] band broadening induced by unfolding generally occurred at a higher temperature for the tentacle material. At lower temperatures, the tentacle material appeared to undergo morphological changes, which influenced the bandwidth of eluted proteins.

An advantage of tentacle gels that has been demonstrated in several difficult protein separations is the low hydrophobic interaction, which results from shielding of the underlying support by an extended layer of ionic polymer combs.[163] For instance, Rögner[592] showed that an early tentacle-type material provided the best separation power for membrane-protein complexes isolated from cyanobacterial thylakoid membranes with detergents above the critical micelle concentration (CMC). Fricke et al.[593] used the low hydrophobicity to purify casein-cleaving membrane proteinase on a strong anion-exchange tentacle material. Purification of these solubilized membrane proteinases could not be done with conventional techniques because the proteins bound irreversibly to all the other stationary phases tested. A high retention ascribed to self-aggregation and strong hydrophobic interactions was also seen with the tentacle materials, but this was solved by an unusual elution scheme with 2-propanol and a decreasing salt gradient. Tentacle materials have superior capabilities of resolving proteins with subtle differences. For example, a cation-exchange tentacle material baseline separated bovine, horse, and rabbit cytochrome *c* variants, native ribonuclease A and its deamidated Asp67 and isoAsp67 forms, and monoclonal antibody variants differing by a single lysine at the heavy chain C terminus, and hemoglobin variants[575] (Figure 42).

Furthermore, flexible ionic tentacles have a unique biomimetic resolving capability for proteins known to interact in vivo with biopolymers having regularly spaced charges. The heparin-mimicking capability of sulfonated tentacle materials has been demonstrated by Cacia et al.,[594] who separated recombinant human deoxyribonuclease I (rhDNase) variants differing in deamidation at a single residue, and by Anspach et al.,[463] who used the heparin-like structure for purification of recombinant human basic fibroblast growth factor.

Separation of proteins and peptides is the main application of IEC, but other charged biopolymers such as polynucleotides,[595] glycoprotein oligosaccharides,[596] and neutral carbohydrates can also be resolved by ion exchange, the latter by high pH anion chromatography.[567] Separations of proteins have been made using anion and cation columns in series and with a singular

Figure 42 CEX chromatographic separation of four hemoglobin (Hb) variants (fetal, sickle cell, normal, and C hemoglobin) on a 250 × 4 mm ProPac SC-10 cation exchanger. Eluent A = 50 mM sodium phosphate and 2 mM KCN to pH 6.0; eluent B = 0.5 M NaCl, 50 mM sodium phosphate and 2 mM KCN to pH 6.0. Gradient = 0–50% B in 30 min at 1 mL min^{-1}. (Reproduced from M. Weitzhandler et al., *J. Chromatogr. A*, **828**, 370 (1998) by permission of Elsevier Science B.V.)

column packed with a blend of anion and cation exchangers.[597,598] However, these dual mode operations do not appear to be widely used.

Binding of biopolymers to the stationary phase takes place from a loading buffer that has its pH adjusted so that the charge of the proteins is opposite to that of the immobilized charged groups of the sorbent (below the p*I* for cation exchangers, and above the p*I* for anion exchangers). The salt concentration should also be sufficiently low to avoid elution of the solutes during loading. Sharpening of the injected band takes place at the top of the column and elution does not occur until the mobile phase composition meets the requirement for solute detachment. Conditions used to promote elution are either an increase in salt concentration or, less commonly, a change in pH towards the p*I* of the adsorbed solutes. A combination of both is also possible. Addition of organic solvents to the eluent can also be used to alter selectivity.[599]

The selectivity can to some extent also be controlled by the type of displacer ions. Kopacievicz and Regnier[572] investigated a number of different salts and classified the displacing capacity of eluent ions from weak to strong. They concluded that the best salts were those where the ions had intermediate eluting capacity, as they were able both to spread out the chromatogram and provide good protein recovery. The same group has also investigated the combined use of salts and solvents to affect retention in HIC and IEC.[260] Hearn et al. studied the effect of different displacing salts on retention and band broadening of proteins in isocratic anion chromatography.[600] The retention order was found to correlate well with decreasing hydrated ionic radii of the eluent anions and the retention was also affected by the type of cation, an effect attributed to preferential interactions with the protein solute. Band broadening was related to Hofmeister effects on the protein and on the double layer interface between the stationary and mobile phases. Malmquist and Lundell employed principal component analysis to find patterns in protein retention data using a large number of salts with cation and anion exchangers at different pH.[601] They concluded that there is a limited possibility of using salts to establish selectivity in IEC, but the most significant effects seen in their experiments were due to changes in the eluent strength of the starting buffer and the alteration of the apparent gradient slopes due to the use of buffer ions of different valence. They also point out that salt effects are more pronounced for late-emerging peaks, which are eluted in a higher salt concentration, and that chaotropic ions are the best candidates for establishing a unique salt-mediated selectivity. Due to the pronounced influence of pH on the charge state of biomacromolecular solutes, proper buffering is obviously very important in IEC. Apart from intended interaction between the ion-exchange surface and the biomacromolecular solutes under study, interactions between solutes and absorbed proteins already present on the surface, for instance due to fouling of the column, should be taken into consideration.[585]

5.5.1 Hydroxyapatite Chromatography

Hydroxyapatite, $Ca_5(PO_4)_3OH$, is a crystalline solid formed by thermal treatment of calcium phosphate[602] in sodium hydroxide solution.[603] The surface affords amphoteric interactions, mediated by the calcium ions and the oxygens attached to the phosphate atoms in the crystal, and the crystal surface offers interaction sites with different properties.[604] Carboxylic groups, basic moieties, and phosphate groups of various biopolymers interact with hydroxyapatite crystals, forming the basis for soft high-capacity multimodal separations.[605] The technique is best characterized as a steric IEC, made possible by the regularly spaced ionic binding sites at the crystalline surface of the sorbent.[606] The separation properties of hydroxyapatite are unique and offer an unparalleled selectivity that can be used to separate proteins that co-elute in other chromatographic modes. As the individual interactions are relatively weak, this method is not well suited for the separation of low-molecular-weight compounds that are only weakly retained. In contrast, the best results were observed for intermediate to large proteins and nucleic acids. The separation mechanism of hydroxyapatite columns, which seems to rely on the formation of complexes between proteins and ions in the mobile phase, was found to control the adsorption of proteins.[607] These processes

can also alter the ionic composition of the hydroxyapatite surface.[122]

The most important applications are separation of subtly different proteins such as antibodies and their fragments,[608] isoenzymes,[609] protein toxins,[608] histone complexes,[610] phosphoproteins,[565] LPs,[611] and solubilized membrane proteins.[612] Hydroxyapatite chromatography can also be used for the separation of polynucleotides such as t-RNA[613] and high-molecular-weight RNA,[614] and glycosaminoglycans.[615] Protein samples are loaded onto the column at a neutral pH from a low concentration phosphate buffer, and the elution is accomplished by a phosphate buffer with increasing concentration at neutral or slightly alkaline pH. Depending on the kind of groups taking part in the interaction and the number of such groups suitably exposed on the solute, the final buffer strength needed to elute the solutes typically varies from 50 to 500 mM. Low column temperatures should be avoided when the more concentrated phosphate buffers are used to prevent the salt from crystallization. The eluent acts by competing with the proteins for the calcium binding sites. Elution can also be effected by other calcium-binding anions such as citrates[565] and volatile ammonium hydrogen carbonate.[616] The common buffer salts such as NaCl or $(NH_4)_2SO_4$ have only a small effect on the retention. Therefore, protein mixtures isolated using other ion-exchange techniques in a NaCl gradient can be loaded directly onto hydroxyapatite columns without previous desalting.[565] A protein separation on a spherical hydroxyapatite column is shown in Figure 43.

Conventional hydroxyapatite suffers from limited mechanical and chemical stability and these properties do not improve even after sintering.[617] The search for mechanically stable materials with hydroxyapatite features had resulted in porous silica functionalized with diol groups and covered with a thin hydroxyapatite layer.[618] Another alternative to hydroxyapatite is ceramic fluoroapatite,[619] which is more stable than hydroxyapatite and has similar chromatographic properties. However, it does not appear to be widely used. The advantageous selectivity of hydroxyapatite has also prompted the investigation of less closely related materials such as lead phosphate hydroxyapatite,[620,621] various metal metaphosphates,[622] and deformed nonporous agarose coated with ferric oxyhydroxide,[623] or aluminum and zirconium (hydr)oxide,[624] onto which phosphate was stoichiometrically bound. All these materials show some features similar to hydroxyapatite, but also large differences. Calcium hydroxyapatite from bones was also evaluated.[15] A different use of the protein-retentive power of hydroxyapatite is in deproteination steps, as part of the sample preparation procedures in the analysis of small molecules.[625]

Figure 43 Separation of standard proteins on a column (135 × 7.8 mm i.d.) packed with spherical hydroxyapatite using a 30-min linear gradient from 5 to 300 mM potassium phosphate buffer (pH 6.8) at 1 mL min^{-1}, and UV detection at 220 nm. Peaks: 1 = BSA, 2 = myoglobin, 3 = ribonuclease A, 4 = lysozyme, 5 = reduced cytochrome *c*, 6 = oxidized cytochrome *c*. (Reproduced from F. Honda et al., *J. Chromatogr. A*, **813**, 27 (1998) by permission of Elsevier Science B.V.)

5.6 Chromatofocusing

Sluyterman et al.[626,627] introduced in 1978 a protein separation technique that can be viewed as a hybrid of IEC and isoelectric focusing. Chromatofocusing, as the technique is called, combines high capacity and high resolution, and has an added benefit of providing an estimate of the p*I* of the eluted proteins,[628,629] which elute at a pH that is determined primarily by their p*I* and secondarily by charge microinhomogeneity on the protein surface.[630] Chromatofocusing is based on the loading of proteins onto a weak anion-exchange column of appropriate buffering capacity that has been equilibrated with a buffer, defining the upper end of the pH gradient to be explored. The proteins are thereafter eluted isocratically with a solution of an oligomeric polyampholyte buffer (a so-called polybuffer), which carries a set of buffering moieties designed to give an even buffering capacity over the separation pH range. The pH of the polyampholyte elution buffer is lower than that of the equilibration buffer and defines the lower end of the separation pH interval. During elution, the polybuffer is titrated by the weak ion-exchange groups on the stationary phase, and pH gradients are thereby formed along the column, both in the mobile phase and on the separation phase. The pH of the eluent decreases in a nearly linear fashion as the

elution proceeds. In general, the starting pH should be above the p*I* of the proteins to be separated (usually 0.5–1 pH unit higher), although this may not always be necessary. Best separations are achieved with shallow pH gradients, which are accomplished by a small pH difference between the equilibrium buffer and the elution buffer, low elution buffer concentration relative to the capacity of the ion exchanger, or a comparatively long separation column. It is essential that the salt strength of the eluting buffer is kept low, so that conventional ion-exchange elution by salt displacement is kept at a minimum. Resolution down to 0.01 p*I* unit differences can be achieved with commercial high-performance chromatofocusing (HPCF) media.[630] A diagram of the gradients developed along an HPCF column during elution with a polybuffer is shown in Figure 44.

Chromatofocusing is one of the mildest of the separation techniques based on pH gradients, due to the fact that proteins are kept in a buffering environment and are not exposed to extreme pHs during the run. In this lies also a risk of aggregation or precipitation of proteins on the column, because the protein surface charge at p*I* is very low, and the colloidal stability of the biomacromolecular solute is hence at its lowest. However, compared to isoelectric focusing, chromatofocusing provides good possibilities of using additives to prevent protein aggregation. Urea, glycerol, ethylene glycol, zwitterionic components, and nonionic detergents can be added at high to moderate concentrations, whereas ionic additives have to be limited to a total concentration of 20–30 mM to avoid salt-induced elution.[630] Another advantageous property of chromatofocusing is high capacity, since a large fraction of the column is used concurrently in the separation process. The separation efficiency is comparable to IEC, but HPCF can be done in shorter time on comparably sized materials.[631]

The columns used for separation are either purposely synthesized to contain a mixture of tertiary amine and quaternary ammonium groups, or anion-exchange columns based on polyethyleneimine. Establishment of chromatofocusing as a high-performance separation technique was done by Hutchens et al.[632] who used PEI-functionalized silica anion exchangers for analytical and preparative separation of estrogen receptor isoforms at good resolution and recovery. Coincidentally, Fägerstam et al.[633] were working with polymer-based mixed strong/weak anion exchangers for fast high-resolution chromatofocusing of human serum proteins, and for studying protein microheterogeneity. Chromatofocusing does not necessarily have to be carried out on anion exchangers. Monkarsh et al.[634] used, for example, a preparative strong cation-exchange sulfopropyl silica column in a quasichromatofocusing set-up with a gradient of acetate/phosphate buffers at increasing pH to resolve two 154-amino-acid fragments of recombinant human interleukin-1α differing by deamidation of one Asn (p*I* 5.1 and 5.3, respectively). In this 75 mL min^{-1} eluent flow rate preparative separation, the use of inexpensive buffer components represents a significant saving

Figure 44 Diagram of the evolution of the mobile and stationary phase pH gradients in chromatofocusing at a starting pH of 10 and a focusing buffer of pH 8. Each curve in (a) represent a gradient inside the column after the stated numbers of eluent aliquots have been pumped. The intersection of these curves with column section 10 (the bottom of the diagram, representing the column outlet) is used to construct the pH profile at the column outlet, as shown in (b). The peak shown as a hatched curve on (b) depicts a protein with p*I* (i.e. elution pH) 9. (Reproduced from L.A. Sluyterman, J. Wijdeness, *J. Chromatogr.*, **150**, 19 (1978) by permission of Elsevier Science B.V.)

Figure 45 Separation of horse myoglobin and bovine hemoglobin on a PBE 94 column presaturated with 0.02 M DEA at pH 9. The eluent was a mixture of 20 mM DEA, 2 mM TRIS and 4 mM imidazole, pH 7, at 0.75 mL min^{-1} flow rate. (Reproduced from R.C. Bates, D.D. Frey, *J. Chromatogr. A*, **814**, 53 (1998) by permission of Elsevier Science B.V.)

over polybuffers. Carboxylic acid weak cation exchangers are also common.

As just hinted, the main drawback of chromatofocusing has been the expensive polyampholyte eluents and special columns that are marketed as a package solution. Furthermore, oligomeric ampholytes are not unproblematic, and unexpected and unwanted interactions have been observed with some protein separations (for a review see Hutchens[630]). Efforts have therefore been made ever since the early days of chromatofocusing to substitute the oligobuffers with simpler buffering components and to use conventional ion-exchange columns for chromatofocusing. Hearn and Lyttle[635] were among the first to evaluate common amphoteric and nonamphoteric buffers in mixtures as development solutions for chromatofocusing on weak anion and cation-exchange columns. Gradients were indeed formed, but their shapes were strongly influenced by the pK_a values of the individual buffer components and did not describe the desired smooth and linear pH changes as a function of elution volume. This work was followed up by Hutchens et al., who developed[636] and applied[637] several multibuffer systems containing up to 34 different buffering substances, and were able to achieve practically linear gradients through the nearly continuous distribution in buffer pK_a, from pH 3.5 to 8.1.

All these studies have been based on internal pH gradient formation, i.e. the isocratic elution buffer and the weak ion-exchange resin are titrated by each other to produce pH gradients both in the mobile phase and on the resin. Results presented by Liu and Anderson[638,639] show that the pH gradient elution technique (termed external pH gradient formation by Sluyterman and Elgersma[626]) can produce linear gradients at the column exit with a weak anion-exchange column using only a few buffer components. Frey et al.[640] developed optimized buffer systems which did not require a buffering weak anion-exchange resin to form a retained pH gradient, and also showed that they could be used for generating quasilinear internal gradients with weak anion-exchange materials[641] (Figure 45).

Linear gradients are necessary when the sample contains many components that are to be separated but, in preparative chromatofocusing, the desired separation can often be achieved with a buffer system showing a few distinct transitions in the right pH intervals. This can also alleviate problems with tailing peaks. Such step gradients can be produced by an internal pH gradient formation with few retained buffer components on a strong ion exchanger.[642,643]

A practical guide to chromatofocusing has been written by Li and Hutchens.[644] Hutchens has also discussed the theory and applications of chromatofocusing, and listed commercially available stationary phases.[630]

5.7 Mixed-mode Interactions in the Chromatography of Biomolecules

Due to their heterogeneous nature, biological macromolecules rarely behave in a chromatographic system as if their retention was controlled by a single separation mode, for which the partitioning between the mobile and stationary phase is expected to change monotonically as a function of changes in the concentration of displacing agent. In reality, the retention is governed to a large extent by factors related to mobile phase interactions, such as conformation changes, precipitation, and ion pair formation. Examples of unintentional multimodality and ways to circumvent this have been discussed in the section on SEC, where enthalpic interaction should be completely avoided, and in HPLAC, where the biospecific interactions should ideally be the only retentive mechanism in operation. The extent of multimodal interaction depends both on the separation mode and on the nature of the solute, and will often result in concave dependencies of retention on the displacer concentration, as illustrated in Figure 46.[81]

These curves illustrate that minimum retention is only obtained in a certain range of displacer concentration. At concentrations below this point, retention is determined

Figure 46 Diagram of typical relationships between retention factor and displacer concentration in HPLC involving multimode interactions. The concave shapes of the elution curves are due to the interplay between the different factors. Fastest elution is achieved in a retention window where the combination of intermolecular interactions between the solute and the mobile and stationary phases favors the solvated state, rather than adsorption to the stationary phase. Curves A to D are explained in the text. (Reproduced from M.T.W. Hearn, C.T. Mant, R.S. Hodges (eds.), *HPLC of Peptides and Proteins: Separation, Analysis and Conformation*, 105–122, by permission of CRC Press.)

by the eluent strength in a conventional sense, as set forth in Equations (18–20). The increase in retention beyond the minimum is due mainly to interactions taking place in the mobile phase, resulting in aggregation of the solutes and their precipitation on the stationary phase. In reality, most biomolecule separations are therefore achieved by means of mixed partitioning and precipitation chromatography.[645] The shapes of the four curves in Figure 46 are explained as follows.[81] Shape A is typical of small polar peptides separated under RP or ion-exchange conditions, and is characterized by a shallow shape according to Equation (18) or (19). The plot has a relatively small k' value as the displacer concentration approaches zero. Retention of these compounds resembles that of small molecules, which can usually be separated isocratically over a wide range of eluent concentrations. Shape B is typical for many polypeptides and fibrous and globular proteins in RPHPLC and in HIC, as well as for most separations in IEC. The most salient feature of shape B is the narrow elution range, which efficiently precludes isocratic elution and makes the separation sensitive to the sample volume and matrix. The retention plot of curve C also exhibits a shallow dependency on concentration, similar to curve A but with a substantially higher value of $\log k'$ at the minimum. The shallow flanks are indicative of a low number of contact points, each having a strong interaction. Curves of type C are typical of hydrophobic peptides under RP conditions, certain proteins in IEC, and some HPLAC and HIC schemes. The most problematic case in represented by shape D, wherein the minimum is sharp and located at high k' value. Therefore, the elution is difficult and low recoveries can be expected. This behavior is characteristic of many membrane proteins in RPHPLC and IEC, and their separation in RPHPLC may require addition of zwitterion pairing agents or detergents in IEC.

If gradient elution is used under sorption conditions described by curves B or D, good recoveries call for the use of relatively shallow gradients, as the solute is capable of traversing the column only within the gradient segment where its retention is at its lowest. If the eluent composition is changing too rapidly, the solute will simply be trapped by the flanks on either side of the eluent concentration of minimum retention, as it is overtaken by the rapidly changing gradient. This will effectively reattach the protein to the stationary phase before it has a chance of being eluted. For that reason, the separation chemistry should be chosen so that k' at minimum retention is unity or less. Once the optimal concentration has been found, recovery can be further improved by applying a more shallow gradient or an isocratic plateau around the critical peak. With Figure 46 fresh in mind, it should be noted that separations showing minima in retention versus eluent strength provide two possibilities of gradient elution: in the conventional fashion, i.e. by increasing the eluent strength (which means increasing eluent concentration except in HIC); and by a retrogradient starting from the opposite eluent composition.[81]

Mixed-mode interactions have been intentionally exploited in order to establish unique selectivities.[646] For instance, Mant et al.[223,224,647–649] have used cation exchangers with hydrophilic supports, operated with organic solvents and salt as eluents, to radically alter resolution between peptides on a single stationary phase (Figure 47). Hirata et al.[650] obtained unique selectivities for peptides on a poly(vinyl alcohol) column with residual carboxylic groups using aqueous acetonitrile as eluent. Floyd and Hartwick used a hydrophobic ion exchanger to separate oligonucleotides in mixed mode,[651] and also presented a review of mixed-mode interactions for separation of biomolecules.[652]

Figure 47 Comparison of RP and HILIC/cation-exchange (CEX) elution profiles of cyclic peptides. RP conditions: linear A–B gradient (0.5% acetonitrile min^{-1}) at a flow rate of 1 mL min^{-1}, where eluent A is 0.05% aqueous TFA, pH 3, and eluent B is 0.05% TFA in acetonitrile. Column temperature 70 °C. HILIC/CEX conditions: linear A–B gradient (2.5 mM $NaClO_4$ per minute, following 5 min of isocratic elution with 100% buffer A) at a flow rate of 1 mL min^{-1}, where buffer A is 20 mM aqueous triethylammonium phosphate (TEAP), pH 3; buffer B is buffer A containing 400 mM $NaClO_4$; acetonitrile is present in both buffers at concentrations of 90% (v/v) in buffer A and 80% (v/v) in buffer B. Column temperature 30 °C. Peptides were detected by their absorbance at 210 nm in both modes. (Reproduced from C.T. Mant et al., *J. Chromatogr. A*, **816**, 88 (1998) by permission of Elsevier Science B.V.)

5.8 Multidimensional Chromatography – Coupled Column Systems

As mentioned above, an orthogonality in separation dimensions is usually necessary to achieve good separations of complex mixtures. Furthermore, as proteins may be thermodynamically unstable but kinetically stable to the chromatographic conditions, separation time and manual handling of solutes are factors working against good overall recoveries. Coupling several separation steps together in a multidimensional system is therefore rational in the separation of biomacromolecules. The distinction between multidimensional and multimode chromatography is sometimes confusing. Multimode chromatography is based on the use of a single separation material with more than one separation principle in operation, a mixture of sorbents in the same column, or columns with different separation dimensions plumbed tandem and flushed by the same eluent.[516] Multidimensional chromatography involves the sequential use of columns with different selectivities in separate runs, operated with a heart-cut or a flush technique to transfer a select portion of the compounds eluting from the first column into the second separation step, a concept that is described by Regnier and Huang.[240]

As opposed to small molecules, where quite incompatible solvents and separation materials have to be used in the different separation steps required to achieve orthogonal selectivities, it should be more facile to couple separation techniques for biomacromolecules because most separations are carried out in fully aqueous eluents. However, whereas coupled-column techniques are frequently used in, for instance, environmental HPLC analyses,[653] surprisingly few automated multidimensional HPLC systems have been described for separation of biomacromolecules. A couple of recent examples are coupling of size-exclusion and anion-exchange chromatography in the analysis of poly- and oligosaccharides,[654] and a process application utilizing an immunosorbent with immobilized protein A connected in series with a quaternary ammonium anion exchanger.[655] An automated system has also been demonstrated for protein primary structure determination, comprising immunoaffinity chromatography, automatic buffer exchange, proteolysis with immobilized trypsin, on-line concentration/desalting, and microbore LC/MS.[656] A few more examples are given in the peptides section.

Timing of eluent transfer to the second column is critical in multidimensional chromatography. It requires experimentally determined retention times and a dedicated instrumentation with exact timing and low dead volume values, and quite complex systems have been designed for use in automated purification, desalting, hydrolysis, and RPHPLC.[657] A persisting problem is drift in retention times of the primary column due to ageing and fouling. But by exploiting the steep elution curves typical of most biological macromolecules, it is often possible to find a binary gradient composition on the first column, so that the retentions of the solutes to be transferred are altered from near infinite to practically nil. Such transitions are usually more dependent on mobile phase conditions than on the state of the separation column. This enables reproducible, efficient and nearly quantitative transfer of the solutes onto the head of the second column where the separation material and the conditions should be the cunning trap that is required to re-establish a sharp injection band.[240] This entrapment is also favored by the U-shaped elution curves, where the minima seldom coincide for different separation chemistries. A particularly promising

field for multidimensional techniques is in combination with MS analysis. Commercial systems with such capabilities have started to emerge.

5.9 Slalom Chromatography

A rather odd separation principle, slalom chromatography,[658] was discovered some years ago, but does not seem to have gained widespread use. Although performed on HPLC equipment, it can in a strict sense not be categorized as a chromatographic technique because the separation takes place entirely in the mobile phase with the packing acting only as a flow-perturbing element. Solutes applicable are large double-stranded DNA molecules (up to 50 kbp), which are separated by means of columns packed with spherical particles similar to those used for high-performance aqueous SEC. The obtained separation is based on molecular size, but smaller molecules are eluted ahead of larger molecules (Figure 48), which is contrary to the selectivity obtained with SEC materials. This inverted retention is due to a hydrodynamic phenomenon occurring predominantly in the mobile phase, whereby larger molecules are delayed because they find it less facile to negotiate optimal flow passages between the particles of the column packing.[659] The technique has a slight similarity to hydrodynamic chromatography,[660] a technique that exploits the nonhomogeneous hydrodynamic fields that exist near the packing surfaces in hydraulically driven flow systems due to the viscous forces. Selective enrichment of larger macromolecules occurs close to the stationary phase due to directed migration transverse to the flow direction, and the technique is used for the separation of high-molecular-weight synthetic polymers and other colloidal particles.

Figure 48 Slalom chromatographic separations of λ/*Hind*III fragments (0, 0.1, 0.05, 0.15, 0.2, 4.4, 6.6, 9.4 and 23.1 kbp) on a Capcell-Pak C1 column. Eluents: 10 mM sodium phosphate buffer, pH 6.8, 1 mM EDTA with NaCl added to 0, 0.05, 0.1, 0.15, or 0.2 M concentration (left to right); flow rate 1.0 mL min^{-1}. (Reproduced from J. Hirabayashi, K. Kasai, *J. Chromatogr. A*, **722**, 137 (1996) by permission of Elsevier Science B.V.)

The dependence on a shear force makes the separation in slalom chromatography reliant on the flow rate of the solution acting as the hydrodynamic selector, i.e. no separation is achieved at low flow rates, with all solutes eluted in the column void volume, and the separation improves steadily as the flow rate in increased. There is also a temperature dependence opposite to normal, with better separations as the temperature is lowered.[659] This technique thus deviates from conventional principles in chromatography in virtually all respects.

The choice of stationary phase appears to be of limited importance,[659,661] but the separation is dependent on minimal partition interaction with the solutes. The particle size determines the molecular size window of the separation[659] – smaller size range DNA molecules are better separated on small diameter packings, whereas larger particles provide improved resolution of large DNA molecules. The solutions used to bring about the hydrodynamic separation are comparatively low ionic strength salt solutions – either purely aqueous, or with a low admixture of acetonitrile.[661] A chapter on slalom chromatography is included in a recently published monograph.[41]

The principle involves accumulation of macromolecular solutes on the surface of the material, and the risk of precipitation should therefore not be neglected, although for molecules with pronounced polyelectrolyte behavior such as double-stranded DNA the risk should be small. It should also be kept in mind that at high flow, the shear forces may reach levels where very large solutes can start to fragment.[662]

6 DETECTION TECHNIQUES

Analytical chromatographic separations would be futile unless a detector device that can provide quantitative (and preferably also qualitative) information is available for monitoring substances eluting from the column. The choice of detector is more important than it might appear at first. It should not only be sensitive enough to detect the eluted species in the required concentration interval, but also comprise an integral part of the overall selectivity of the method. Accordingly, detectors based on a variety of principles have been developed for use in HPLC, and their principles and characteristics have been covered in several monographs.[663–666] A variety of often conflicting criteria determine the applicability of a detector. The sensitivity should be sufficient, with a linear response spanning the entire analyte concentration range. It should give stable signals and show a good reproducibility at a low noise level. The response should be fast and the internal volume minimal with a flow geometry optimized

to minimize band broadening. Low sensitivity to changes in eluent temperature and RI are important, particularly in gradient elution. When hyphenated systems are used, or when the separated compounds are collected for further analysis, is should be verified that the detector does not alter the solutes on passage through the detector. The reliability and user-friendliness, i.e. the level of expertise required to operate the detector, are also very important in real laboratory settings, so that the operator can easily identify a malfunction and understand how to correct it.

The detector should either give identical response to all solutes, or a highly selective response towards one or more classes of solutes. As mentioned, the detector is an important part of the overall selectivity optimization of an analytical separation. If the detector is sufficiently selective yet has a general response, the chromatographic separation process could in principle be disposed of, because the detector would be capable of both resolving and detecting the analytes in a non-chromatographic process. Examples of such detectors are mass spectrometers, notably matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI/TOFMS), described elsewhere in this encyclopedia.

Detectors are usually classified according to their response pattern as general or selective. A general response has a wide scope, as a single detector can be used to detect many different compounds, but also requires that the compounds presented to the detector are completely resolved. A distinction is often made between bulk property and solute property detectors, where a bulk property detector measures the changes in a bulk property of the eluent, such as RI, as a solute elutes. Characteristic of bulk property detectors is their low selectivity and sensitivity, but this is not always a drawback. Worse is their sensitivity to variations in eluent composition, which effectively precludes their use in gradient elution. Solute property detectors are designed to measure changes in a property expressed by the eluted solutes, but not by the eluent. By tuning the detector to a common property of the solutes, it is then possible to determine these in the presence of an eluent of changing concentration. A selective detector is usually tunable, whereby a discrimination of co-eluting compounds may be possible.

Most detectors are spectroscopic, i.e. they measure the interaction of solutes with electromagnetic radiation. Different wavelength regions provide access to different kinds of information and offer unique possibilities to tune the selectivity. Quantitative information is denser in some spectral regions, whereas other regions offer higher absorptivity and thereby better sensitivity, and freedom in the choice of solvents. These factors explain the persistent use of UV spectrophotometry, although the information density provided by electron excitation in solution is rather meagre. A universal feature of proteinaceous matter is the peptide bond, which absorbs strongly in the far UV, below 220 nm. A narrow window for general detection thus exists in the wavelength range 210–220 nm, below which noise and solvent absorption tends to become troublesome. Disulfide bonds absorb in the 250 nm region, and the aromatic side-chains of phenylalanine, tyrosine, and tryptophan absorb in the wavelength range 250–300 nm. The absorption band of nucleotide bases lies in the vicinity of 260 nm. Carbohydrates lack chromophores in the accessible UV region. When several absorption bands are available, the longer wavelength absorptivity is often weaker. However, the actual signal-to-noise ratio, as determined by the presence and variability of spurious peaks in the vicinity of the solute (chemical background noise), is usually better because nonsolutes rarely absorb UV light at long wavelengths. Furthermore, intensive low-wavelength UV radiation can cause bond dissociation and trigger other photochemical processes that alter the solutes on passage through the detector.

DADs are absorbance spectrophotometers capable of measuring the entire UV wavelength range simultaneously in real time using integrated photodiodes as sensing elements.[665,667] Their price is low when considering the flexibility and the amount of information provided, and modern DADs are good alternatives to conventional single-wavelength UV detectors. There is a principal and important difference between multiwavelength DAD and conventional single-wavelength UV spectroscopic detectors, evident in Figure 49. In a single-wavelength detector, the eluate is illuminated by a single wavelength and the transmitted light is measured by a single photodetector. In order for multiwavelength detection to be feasible in a DAD, the sample has to be illuminated with light of the entire spectral range being measured (usually 190–380 nm), which means that photochemically sensitive substances are prone to undergo photochemical reactions[668] on their passage through the detector. In a purely analytical setting this may not be troublesome, unless artifact signals are produced from irreproducible bleaching or formation of new compounds in the detector cuvette. However, photochemical processes must be considered if the separated compounds are collected for further investigations.

Fluorescence detection is based on emission of light following photoexcitation and is a native property of some biological molecules, notably polynucleotides and aromatic peptide lateral groups. Fluorescent properties can also be introduced in molecules by derivatization (see below). As opposed to spectrophotometry, where the measurement is based on log transformation of subtractively measured absorbed light, fluorescence is at low solute concentration a linear function of the solute concentration and the intensity of the incident beam. The

Figure 49 Optical and flow cell components of a single-beam diode array detector using reversed optics, meaning that all the light from the lamp passes the flow cell before reaching the wavelength-dispersive element, where it is separated into its spectral components and projected onto the photodiode array. (Reproduced by permission of Hewlett-Packard Company.)

emitted light is collected perpendicular to the excitation beam and the need to extract the signal by subtraction is thereby eliminated, enabling sensitive and selective detection. Selectivity is further enhanced as few molecules absorbing light are capable of fluorescing. A suitable entry point to this literature can be the recent review of Tao and Kennedy on laser-induced fluorescence detection in microcolumn separations.[669]

Chiroptic detection based on measurement of circular dichroism (CD), i.e. the difference in absorption of the clockwise and counter-clockwise rotated vector components of a polarized light beam passing through a medium containing a chiral component, has been used for a long time in HPLC.[670] The CD principle is also widely used for determining the secondary structure of proteins, because of the chirality of amino acids and the spontaneous organization of polypeptide chains in either left- and right-twisted α-helices and β-pleated sheets, or as a random coil, producing a characteristic optical rotation and CD spectra. Thus, CD detectors can provide information on the conformation of eluted proteins.[671] The main drawback of CD detectors is their limited sensitivity, which restricts their use to separations carried out on high-capacity materials, where the concentration of protein is relatively high.[672]

Vibrational spectra carry more information than the electronic excitation spectra obtained in the ultraviolet/visible (UV/VIS) region. However, infrared spectroscopy detection is not a viable alternative, because the solvents used for the separation of biomacromolecules are not transparent in the infrared region. Raman spectroscopy has been used sporadically as a detection principle in HPLC. For instance, purine bases have been detected by on-line surface-enhanced Raman spectroscopy after mixing with a silver sol.[673]

Modern high-field nuclear magnetic resonance (NMR) spectroscopy provides an extremely powerful tool set for characterization of biological macromolecules and their interactions. However, although direct coupling of NMR to HPLC has been successfully utilized for structural elucidation of small molecules,[674] the long time required for obtaining spectra for large molecules has prevented the use of LC/NMR for on-line characterization of eluted biomacromolecules. When NMR spectroscopy is used in combination with HPLC of biomacromolecules, eluted peaks should therefore instead be collected and subjected to off-line spectroscopy.

RI detectors measure changes in the index of refraction of the eluent induced by the solute. In principle, all solutes affect the eluent RI, but the sensitivity varies, and compounds lacking absorption or other properties enabling selective detection can often be detected by RI detection. The drawback of RI is that it is a bulk property of the eluent, which makes the detector signal very sensitive to eluent composition and effectively precludes gradient elution. As the majority of all separation schemes

for biomacromolecules require changing eluent composition, RI detection is usually impossible. An exception is high-molecular-weight carbohydrates, for which separation often takes place in SEC and where the lack of chromophores has been a persisting problem. Differential RI detection is thus still used, often hyphenated with other measurement principles. Recent developments have alleviated the temperature sensitivity and improved the detection limit substantially.[675]

Related to RI detection, although with a radically different sensitivity and degree of sophistication, is surface plasmon resonance, a principle used in the leading biosensor system. The small biosensor detection volume makes it suitable for use as an HPLC detector,[676] in particular in affinity chromatography.[677,678] This and other biospecific detection principles have been reviewed.[679]

Due to their size, biomacromolecules are good scatterers of light in solution, which forms the basis for the low-angle laser light scattering (LALLS) and MALLS principles that have been introduced to LC detectors in recent years. Both of these measurement principles can provide information on the molecular weight of macromolecules, thus supplementing external calibration in SEC. The additional information provided by multiple measurement angles in MALLS also provides information on the radius of gyration, so that characterization of both the molecular mass and the shape of biomacromolecules can be carried out on line.[680] An example of a SEC separation with MALLS and differential viscosity detection is shown above (Figure 16). A commercial detector is also available where the scattered light is measured at right angles (RALLS). This detector is combined with an RI detector and a viscosity detector based on measuring the differential pressure across a detector cell containing multiple capillaries for determining association and rheological phenomena of high polymers.

A different scattering principle is used in evaporative light scattering detection (ELSD), where the signal is based on light scattered from a dried aerosol produced by spraying the eluent into a desolvating chamber and evaporating the solvent and other eluent components. Nonvolatile solutes form microparticles that are detected in the gas phase as they pass the detection cell. The technique has become particularly popular in the separation of lipids and related substances, and for carbohydrates. An entry point to the literature can be a recent review of its use in combinatorial chemistry.[681]

Many electrochemical detectors exist, but the mode particularly interesting for biological macromolecules is pulsed amperometric detection (PAD),[682] because it is capable of detecting polar aliphatic compounds containing alcohol, amine, and thiol groups that are not easily detected by photometric or fluorimetric techniques. The PAD technique uses a pulse sequence to adsorb compounds on a platinum or gold electrode surface and then selectively oxidize the deposited compounds, followed by a cleaning sequence where adsorbed material is oxidatively removed from the surface prior to the next pulse sequence. The strongly adsorptive properties of noble metal electrodes, which are problematic under nonpulsed conditions, are thereby mastered and turned into an advantage and the PAD technique has become the preferred non-MS detection method for detecting carbohydrates.

Almost general yet highly selective, MS is close to fulfilling all requirements of an ideal detector. Its extremely high sensitivity coupled with a multitude of ionization and fragmentation techniques makes it capable of providing sufficient information to resolve the structures of complicated biological macromolecules. The ease of using a mass spectrometric detector has improved vastly, and it is now an accessible technique even outside the most sophisticated laboratories, which makes it a serious competitor to the techniques listed above. However, the cost of buying and operating an MS detector is still high compared to the alternatives. Traditional detectors will therefore still exist alongside MS for a long time where their performance is adequate. The LC/MS combination forms an extremely powerful tool for structural elucidation of biomacromolecules, a topic dealt with in other parts of this encyclopedia.

6.1 Labeling Reactions for Introduction of Detectable Properties

Intrinsic properties such as UV absorption, native fluorescence, or electrochemical activity form the basis of most detection schemes in HPLC and sufficient detection limits can usually be obtained with substances in their native form. However, in trace work, the sensitivity achievable by the use of intrinsic properties can be insufficient, and it may therefore be necessary to resort to derivatization, i.e. enhancing the detectability of solutes by introduction of a detectable property through chemical reactions. These reactions can be carried out either before the sample is injected (precolumn), or after the sample has been separated (postcolumn). Derivatization techniques targeting functional groups present in biomacromolecules have been described in several books.[668,683–686] Two recent reviews by Krull et al.[687,688] focus on derivatization and detection of proteins, Koller and Eckert have reviewed derivatization of peptides,[689] and Boppana and Miller-Stein gave an outline of pre- and postcolumn derivatization techniques for sensitive detection of peptide drugs.[690] A sensitive separation of peptides with ninhydrin postcolumn derivatization is shown in Figure 50.

Figure 50 Endogenous peptides separated on a C_8 silica column (250 × 2.0 mm i.d.; 5 μm) and detected by postcolumn reaction with ninhydrin. Mobile phase: monochloroacetate buffer (65 mM, pH 3.2) with 10 mM sodium octanesulfonate and methanol (55 : 45 v/v initial; following injection, the methanol was increased to 70% in 30 min and held for 30 min). Temperature 60 °C. Peak identities and amounts injected: 1 = desglycylamide vasopressin (39 pmol), 2 = Arg-vasopressin (41 pmol), 3 = luteinizing-hormone releasing hormone (18 pmol), 4 = angiotensin II (20 pmol), 5 = bombesin (13 pmol), 6 = bradykinin (8 pmol), 7 = angiotensin III (22 pmol), 8 = angiotensin I (16 pmol), 9 = atrial natriuretic peptide (7 pmol), 10 = ACTH (6 pmol), 11 = growth-hormone releasing factor (4 pmol). (Reproduced from V.K. Boppana, C. Miller-Stein, *Anal. Chim. Acta*, **352**, 67 (1997) by permission of Elsevier Science B.V.)

Precolumn derivatization uses polar functional groups in the solute to attach a tag, i.e. a chromophore, a fluorophore, an electrophore, or a moiety within a characteristic fragmentation pattern in MS. The derivatized analyte is then separated and detected through the properties of the attached tag. A wide variety of labeling reagents are available, targeting amino groups, hydroxyl groups of different reactivity, carboxylic acids, keto and aldehyde groups, etc. The tags originally introduced were promoting UV absorbance, but over the years derivatization for fluorescence detection has become more common. The detection limits obtainable by fluorescence derivatization rival those obtainable in MS, so fluorescence detection may be an alternative worth considering if the added identification and structural elucidation possibilities of MS are not needed. Precolumn derivatization reagents and their break-down products usually display the detectable property, and excess reagent will therefore be visible in the detector, although eluted at a different retention time. The reagent is therefore usually added only in moderate excess relative to the target functional groups, to avoid large spurious peaks in the chromatograms. At low analyte concentrations, reaction speed will be radically decreased because both the reagent and solute are reactants in a bimolecular reaction. Ways to circumvent this are to add more reagent and remove the excess reagent by extraction, or to allow it to react with a solid carrier containing functional groups reacting with the reagent. When considering whether or not to apply a derivatization scheme, it must be taken into account that precolumn derivatization alters the retention properties of the analytes, so that existing separation schemes have to be modified. An altered retention pattern can also be the reason for carrying out a derivatization, e.g. by reversible attachment of chiral fluorescent groups[691] or fluorescent groups capable of expressing affinity interactions.[692] Derivatization of biopolymers is complicated by the possibility of multiple derivatization on several reactive groups, leading to multiple products from a single solute molecule. Although this carries a potential for more sensitive detection, it is likely to lead to splitting of solute peaks in the separation step. A monumental handbook of derivatization techniques for HPLC was published recently.[693]

Postcolumn derivatization is based on separating the analytes in their native form, then subjecting them to a derivatization reaction after the sample has passed the column. This means that existing separation schemes can be used, provided the eluent is compatible with the postcolumn derivatization reaction. The reaction is carried out on line by adding one or more reagents to the eluate and allowing sufficient time for the reaction to take place before the sample is passed into the detector. Successful use of postcolumn derivatization calls for reagents acting as a precursor of the detectable property, i.e. the reagent itself should not be visible

to the detector, but be converted into a detectable moiety on reaction with specific functional groups in the solutes. As in precolumn derivatization, reaction kinetics is central and reaction time must be gained by delaying the eluent–reagent mixture on its way to the detector. Various means of accomplishing delays without excessive band broadening have been described in the literature but some deterioration of the separation efficiency is inevitable. The books referenced above provide more information on applicable techniques.

7 SAMPLE PREPARATION

General guidelines for preparing samples are difficult to give, because the diversity of biological macromolecules and the matrices in which they exist is infinite. A few key concepts are nevertheless important to convey. The most prominent feature of material derived from living organisms is biological activity, and cellular processes are characterized by a continuous reconstruction through simultaneous enzyme-catalyzed metabolic and catabolic processes. Metabolic break-down of macromolecular components by controlled enzymatic processes is a central part of a system where building units are extensively recycled and, in a living cellular system, sensitive molecules are separated from metabolic processes by membranes and other barriers. A controlled exchange of material takes place with the surrounding tissue or medium through these barriers in processes driven by energy. When the system is disturbed, it will attempt to accommodate to the changes by altering the cellular processes, and if the perturbations are sufficiently large, the system collapses and the cells will die. However, this does not mean that all processes taking place in the cell will cease, only that the pathways and the mechanisms will be different, and in the absence of added energy the metabolic processes will prevail. As the energy required to maintain order ceases to flow, components normally kept separate can come in contact.

What this dramatic account of impending chaos and disorder intends to tell is the importance of knowing the history of a sample, and to control processes that lead to alterations of samples. In general, a biological sample should be subjected to analysis as soon as possible after isolation. If this is not possible, appropriate measures should be taken to ensure that the components of interest are not subject to changes by biological or chemical processes. There are numerous ways to store a sample, and the more common are freezing and lyophilization. Both these processes will lead to disruption of membranes in tissue samples, so that most components will be in contact with each other when the sample is thawed or rehydrated. Such samples are therefore particularly prone to alterations. Of particular concern are proteolytic enzymes, which exist in all biological systems. If left to operate on a cell suspension, they will rapidly lead to significant alterations. Other enzymatic processes can also cause changes to the samples. Obviously, this breakdown or alteration will largely cease if the analytes are separated from the enzymes responsible for catalyzing the changes, or if these enzymes are inhibited. Metal-complexing agents such as EDTA and EGTA (ethyleneglycol bis(aminoethyl)tetraacetic acid) are widely used and protease inhibitors are available singly or in mixtures for adding to samples in order to prevent break-down. Hassel et al. recently published a study of ways to eliminate unwanted proteolysis during extraction of proteins from protease-rich tissue,[694] and came up with a rather complicated mixture of inhibitors and metal-complexing agents. However, this should only be regarded as a first aid, as addition of reagents complicates the matrix and addition of foreign biological material compromises the integrity of the sample. Also, protection by recognized synthetic or biological protease inhibitors cannot be entirely relied upon, as is evident from accounts in the literature.[695,696] The key rule is to keep the samples on ice, and to initiate the preliminary sample clean-up steps as soon as possible, in order to separate deleterious components from the analytes. Keeping samples cold also helps maintain the biological activity of sensitive proteins that may be rapidly denatured when the cellular environment is disrupted. Detergents may be needed to get and keep solutes in solution, such as use of the mild nondenaturing detergent Triton X-114 as a phase-partitioning agent in the purification of plant proteins.[697] Micelles may also be valuable, as in the extraction of hydrophobic peptides.[698] Partitioning in aqueous two-phase systems is a batch-operated soft-separation process for cells, organelles, and membranes,[699,700] that can be used as a sample preparation step for high-performance separation.[414,701]

Reviews have been published on sample preparation and column regeneration in protein separations,[702] sample preparation and separation of food-derived peptides,[703] the use of solid-phase extraction for preparation of catecholamines and biologically active peptides,[704] on hydrolysis and amino-acid composition analysis of proteins,[705] and on enzymatic digestion of DNA for determination of nucleotide composition.[706] Solid-phase extraction on a weak cation exchanger has for example been used to quantitatively extract and concentrate peptides from plasma samples with simultaneous removal of endogenous interferents.[707]

Other processes leading to alterations of a sample are changes in the redox state and the influence of light. Although the latter factor is simple to control, it is more difficult to control the redox potential in a sample,

which can have significant impact on thiols, disulfide bridges, conjugated phenols, and other easily oxidized or reduced moieties in biological macromolecules. Addition of 2-mercaptoethanol or dithiothreitol is common in order to prevent oxidation of methionine[708] or to break disulfide bonds in difficult-to-extract proteins, such as hair.[709] The final culprit is surface adsorption of trace amounts of biopolymers, which should be controlled by the same intuition that guides the choice of stationary phases and eluents in LC.

8 PREFERRED SEPARATION TECHNIQUES FOR DIFFERENT CLASSES OF BIOMACROMOLECULES

Descriptions of the various techniques presented above have listed numerous examples of separations for each separation mode. The other dimension into this vast field is application-oriented. The exceptional variation in biological macromolecules and the size of the field make it impossible to cover applications except in summary, and the best way is to guide the reader to recent relevant reviews.

8.1 Oligonucleotides and Polynucleotides

Separation of polynucleotides is nowadays a stronghold of electrophoretic separation techniques, the most important being Southern and Northern analysis,[710] and capillary gel or zone electrophoresis.[711,712] However, liquid chromatographic techniques have been important in nucleic acid research, often in combination with electrophoretic techniques,[713] and are still widely used for clean-up, sample preparation, and for analytical separations.[714] Polymeric nucleic acids are linear polyanions, where the chains are held together by phosphodiester links between the 3′ and 5′ hydroxy groups in the (deoxy)riboses of adjacent nucleotides. The negative charge comes from the phosphodiester links, but there are also positive charges from some of the pyrimidine or purine bases of the nucleotides. In a homopolymer, the charge will increase linearly with length but, as natural nucleic acids are heteropolymers, charge cannot be directly correlated to the length of the polynucleic acid. Separations are also complicated by the formation of complexes between nucleic acids. These interactions can take the form of hair-pin turns within the same molecule, bonding between adjacent chains, or association to hydrophobic sample components.

Both hydrogen bonding and hydrophobic forces are important in the intermolecular interactions of nucleic acids. Presence of water diminishes the importance of hydrogen bonds, but in oligonucleotides the bases are stacked because of hydrophobic π-electron interactions between the aromatic bases. This stacking prevents water from accessing the hydrogen bonding sites of the bases, and strengthens the interchain binding. The hydrophobic interactions can be broken by solvents, so that water is provided a better access. Water then competes with the bases for the available hydrogen bonding sites, which weakens the bonding between base pairs. Many RPHPLC solvents are capable of mediating this breaking of hydrogen bonds. Because of this dual mechanism, these solvents can be used not only to control the retention in RPHPLC, but also to increase the retention in anion-exchange chromatography of oligonucleotides. Interchain hydrogen bonding is furthermore affected by the structure of water, whereby chaotropic salts tend to break up hydrogen bonding, whereas cosmotropic salts increase the structure and should be avoided in the separation of ''sticky'' oligonucleotides. Increased temperature also promotes dissociation of bonds between oligonucleotide chains. Applicable HPLC separation schemes are consequently based on hydrophobic interactions (RP), ionic interactions (anion exchange), and hydrophilic interaction. Metal systems should be avoided because phosphate groups bind strongly to metals. Addition of phosphate to the buffer will decrease interactions with metals. A separation of a DNA digest by anion exchange is shown in Figure 51.

Retention in RPHPLC is due to the aromatic character of the bases, and can be altered by the addition of an alkylamine ion pair reagent to the eluent, effectively transforming the separation into a mixed-mode reversed-phase ion-exchange chromatography (RPIEC). Separation materials with shorter alkyl chains are often preferred over octadecyl silica, as the retention with the latter phases tends to be high. Except for very short oligonucleotides, elution must be done with gradients. In anion-exchange chromatography, retention is controlled by salt concentration, pH, and admixture of solvent, which is recommended to break hydrophobic interactions. Because the charge is increasing rapidly with increasing size, elution has also here to be accomplished by gradients. Contrary to RP, retention in anion chromatography increases with solvent concentration.[716]

A comprehensive coverage of nucleic acid separations was the subject of a special issue of *Journal of Chromatography* (Vol. 806:1). It is significant that a majority of the papers dealt with electrophoretic or other nonchromatographic techniques, but HPLC is nevertheless being used. Two of the chromatography papers were reviews and treated the use of micropellicular anion-exchange and ion-pair RP stationary phases and optimization of gradient elution parameters in the separation of double stranded DNA[715] (includes a table comparing anion-exchange and ion-pair RP DNA separations), and displacement chromatography in the purification of

Figure 51 Separation of a pBR322 DNA-*Hae*III digest on (a) a micropellicular and (b) a macroporous anion-exchange stationary phase. Conditions in (a): column, TSKgel DEAE-NPR (2.5 µm, 35 × 4.6 mm i.d.); mobile phase, (A) 20 mM TRIS-HCl, pH 9.0, (B) 1 M NaCl in 20 mM TRIS-HCl, pH 9.0; linear gradient, 25–45% B in 0.1 min, 45–50% B in 2.9 min, 50–100% B in 57 min; flow-rate, 1.5 mL min^{-1}; temperature, 25 °C; sample, 4.8 mg of pBR322 DNA-*Hae*III digest. Conditions in (b): column, Mono Q (10 µm, 700 Å pore size); mobile phase, (A) 20 mM TRIS-HCl, pH 8.3, (B) 1 M sodium chloride in 20 mM TRIS-HCl, pH 8.3; linear gradient, 40–65% B in 2.2 h, 65–75% B in 5.8 h; flow rate, 0.15 mL min^{-1}; ambient temperature; sample, 20 mg of pBR322 DNA-*Hae*III digest. synthetic oligonucleotides and nucleic acids.[717] The analysis of DNA adducts by capillary HPLC and CE coupled to MS was reviewed by Apruzzese and Vouros,[718] who discussed the entire analysis chain with extraction, hydrolysis, enzymatic digestion, and solid-phase extraction or HPLC as sample preparation steps. The use of LC/MS for the characterization of nucleosides, nucleotides, modified nucleotides, oligonucleotides and DNA adducts was reviewed by Esmans et al.,[719] collating the procedures for the analysis of oligonucleotides in a diagram. The preferred technique is HPLC with electrospray MS. Techniques for the detection of damage to DNA were reviewed by Cadet and Weinfeld[720] and by Frenkel and by Klein,[721] and the use of HPLC for recognizing covalent modifications to nucleic acid by anticancer drugs was reviewed by Cummings et al.[722] Size-dependent chromatographic separation of nucleic acids, in particular slalom chromatography, was reviewed by Kasai,[658] and the use of nucleic acid polymers immobilized on solid supports for affinity chromatographic isolation of polynucleotides and polynucleotide binding proteins was the subject of a review by Jarrett.[472]

The use of three acrylate-based SEC columns with different molecular weight cut-offs connected in series was described by Franek and Koutnik to separate oligonucleosomal DNA fragments from apoptotic animal cells with molar ammonium acetate as eluent.[723] Itoh et al. used a fluoroalkyl silica that was converted into a mixed-mode sorbent by treatment with trioctylmethylammonium chloride for separation of various nucleic acids by gradient elution with either an acetonitrile solvent gradient or a perchlorate salt gradient.[724] Good separations could be obtained by both elution mechanisms. The mixed mode could be used for separations of up to 40-mer oligoadenylates, and for oligocytidylates, oligodeoxynucleotides, and t-RNA. Chromatography on strong anion-exchange columns has been used for the preparative purification of supercoiled plasmid DNA.[595] Ion-pair HPLC could resolve three components in a reverse transcriptase chain reaction product, whereas only two components were detected by agarose gel electrophoresis.[725] An example of RP separations of DNA digests is shown in Figure 52.

Transfer-RNA has been separated by gradient elution on hydroxyapatite, and it was found that increased pH caused a stronger bonding of t-RNA to the stationary phase, a retention dependence opposite to proteins.[613] A mixed-mode separation on aminopropyl silica modified with alkyl groups, mainly according to the HIC mode, has also been used for t-RNA.[726,727] High-molecular-weight RNA has also been separated on hydroxyapatite following dissolution in guanidinium isothiocyanate.[614] A way to accomplish 5′-aminoalkyl labeling of DNA oligomers through *N*-hydroxysuccinimide ester activation and separation of the resulting derivatives was described by Wang et al.[728] Mixed-mode separation of nucleic acids has also been reviewed.[729]

8.2 Peptides

Peptides are small proteinaceous compounds, ubiquitous in living creatures and in the natural environment.

Figure 52 Chromatogram of pBR322-*Hae*III digest (0.75 µg) and pBR322-*Msp*I digest (0.4 µg) on a PS-DVB-C_{18} RPHPLC column (50 × 4.6 mm i.d.) with elution optimized for separation of the large number of fragments (size indicated by labels). Mobile phase composition: A = 0.1 M triethylammonium acetate (TEAA), pH 7.0; B = 0.1 M TEAA pH 7.0, 25% acetonitrile. Gradient: linear 37–55% B in 6 min; 55–65% B in 14 min; flow rate, 1 mL min^{-1}; temperature, 55 °C; detection, UV as 254 nm. (Reproduced from P.A. Doris et al., *J. Chromatogr. A*, **806**, 49 (1998) by permission of Elsevier Science B.V.)

When actively produced by organisms, peptides tend to have highly specific tasks and their biological activity is usually expressed at very low concentrations. Isolation of peptides is therefore important in biosciences, both for analytical purposes and as preparative steps in biological and biomedical research. Because of their potential activity, it is also essential that peptides synthesized for research or therapeutic use are efficiently purified before being used in biological systems,[730] a task often accomplished by preparative HPLC. Peptide separation is furthermore a central part of peptide mapping schemes (Figure 53) for elucidating protein structure.[731,732]

The distinction between a peptide and a protein is somewhat arbitrary, but it is common to refer to amino acid sequences with 50 residues or less as peptides. The properties differ widely in this range – dipeptides are small molecules and behave chromatographically as such, with shallow retention curves and retention more or less directly related to the properties of the constituent amino acids. Large peptides with M_W of several thousand daltons differ little from proteins in their chromatographic behavior and follow the multiple interaction mechanisms outlined in the introduction. Under favorable conditions, peptides lack secondary structure such as α-helices up to a size of about 15 amino acids. When peptides exceed this length, the likelihood of secondary and tertiary structure increases[733] and, towards the upper size limit, peptide chains are prone to fold in order to internalize side-chains of low polarity.[734] This has a pronounced effect

Figure 53 Optimized and (A) aseptically and (B) nonaseptically processed (2-h trypsin digest at ambient temperature) protein C peptide map on a Zorbax 300SB-C_{18} (4.6 × 250 mm) column at 35 °C. Mobile phase A, 0.1% TFA in H_2O; mobile phase B, 0.08% TFA in 80% acetonitrile and 20% H_2O, at a flow rate of 1 mL min^{-1}. Samples injected: 100 µL; 0.25 mg mL^{-1}. Detection: UV at 214 nm (1 AU/V). (Labels refer to tryptic fragments used in a validation procedure.) (Reproduced from A.D. Carlson et al., *Anal. Chim. Acta*, **352**, 227 (1997) by permission of Elsevier Science B.V.)

Table 8 Summary of HPLC separation techniques commonly used to separate peptides

Separation mode	Use	Typical eluents
SEC	First separation step, isolation of peptides from proteins and other large molecules. Columns with pores separating from 100 to 7000 Da are available for analytical separations.	Water with the addition of buffer and salt at a concentration sufficiently high to suppress adsorption tendencies due to residual ionic charge on the stationary phase.
IEC	Gaining in popularity because small changes in pH can give large changes in selectivity. Ion exchange materials with high separation efficiency have also become available.	Cation-exchange mode is favored, at least with silica-based materials. Buffers are typically weakly acidic. Elution can be carried out by salt or pH gradients.
RPHPLC	The most popular technique because of the high separation efficiency, the wide scope, and the relative stability of peptides, compared with proteins.	Gradients of water-miscible organic solvents (acetonitrile is often preferred) in acidic buffers. The buffer anion can have an effect on selectivity.

on the apparent hydrophobicity and the dissociation constants of ionizable side-chains in the native state. The presence of disulfide bridges also contributes to conformational changes, and depends on the oxidation state of the peptide. All factors leading to alterations in conformation must be considered and brought under control when a method is developed, because they may have a large impact on the chromatographic behavior of a peptide.[125]

Separation schemes for peptides are often complex, especially when the analyte exists in a biological matrix. Combinations of chromatographic techniques with orthogonal separation dimensions are therefore regularly employed. Because of the relatively low molecular weight and reasonable stability of peptides, a variety of HPLC subtechniques which would lead to irreversible sorption or denaturation of larger biomacromolecules may be applicable. The most popular separation modes are SEC, IEC, and RPHPLC. The initial separation steps usually aim at isolating the molecular weight fraction of interest from proteins and low M_W matrix components. Final separations of the peptide fraction are then carried out with techniques that capitalize on differences in hydrophobicity or net ionic charge. Gel electrophoresis and capillary zone electrophoresis (CZE) are useful for verifying the purity of separated peptides, as their separation principle based on differential migration in electric fields is markedly different from chromatographic partitioning. Table 8 summarizes the most important HPLC techniques used in the separation of peptides. As can be inferred from their biological significance, separation of peptides has been the subject of numerous monographs[73,735–738] and a large number of review articles, of which a select number are referred to below. Recent practical reviews have been written by Mant and Hodges,[125] and by Lundell.[739]

SEC is often used as the first step in a multistep peptide separation protocol or for separation of peptides from proteins. The most frequently used columns are silica

Figure 54 Separation of standards on a Superdex Peptide HR 10/30 column (10 × 306 mm). Sample: 25 µL, 0.2 mg mL^{-1} of each polypeptide (1–6) and 7.8 mg mL^{-1} of glycine (7). Mobile phase: 20 mM phosphate buffer, pH 7.2, containing 0.25 M NaCl; flow rate 0.5 mL min^{-1}. Standards, with molecular weights (Da) in parentheses: 1, Cytochrome *c* (12 500); 2, aprotinin (6500); 3, gastrin I (2126); 4, substance P (1348); 5, Gly_6 (360); 6, Gly_3 (189); Gly (75). (Reproduced from G.B. Irvine, *Anal. Chim. Acta*, **352**, 392 (1997) by permission of Elsevier Science B.V.)

with pore sizes of 60–150 Å. These columns are designed for SEC of proteins and the molecular weight range is thus inoptimal for separation of peptides. Polymer-based columns designed for optimal separation of the molecular weight range 100–7000 Da are commercially available and have been successfully used in the SEC separation of peptides[740] (Figure 54). The general precautions outlined above apply to peptides. Self-association and interaction with other biomacromolecular solutes can also affect their separation. The use of denaturing conditions,

such as by the addition of urea, may therefore be necessary to ascertain that the peptides are monomeric. The theoretical and practical aspects of high-performance SEC of peptides was recently reviewed by Irvine.[741]

RPHPLC of peptides is typically run on silica columns with linear alkyl functional groups (C_4 to C_{18}) of 100–300 Å pore size, with gradients of 2-propanol, acetonitrile or methanol. Some TFA or another acid (see above) is added to the eluent in order to suppress the dissociation of surface silanols, and to accomplish an ion pairing with basic amino acid side-chains. Due to the reasons outlined under mixed-mode interactions above, gradient parameters may be critical to success. A gradient should always start from a low concentration of organic modifier, not pure water, because the layer of alkyl chains on RP stationary phases can collapse in entirely aqueous eluents. The best separations are usually obtained with relatively shallow, linear gradients. The final concentration of organic modifier is typically between 50% and 100%, which means that the solubility of ionic mobile phase additives should be checked at the highest modifier concentration. Extremely hydrophobic peptides may require special eluents and solvents.[742] The column temperature can be used to fine tune the retention through temperature-induced conformation changes of peptides in contact with the stationary phase. A slightly increased temperature can also improve the separation efficiency because the eluent viscosity decreases, affecting the diffusion coefficients positively. A comparison of RPHPLC and transient isotachophoretic CZE for the determination of peptides in plasma has been published.[707] The related but softer separation principle of HIC is useful for separation of larger peptides, whose secondary structure is creating problems in RPHPLC, or if denaturation is an issue.[99]

Synthetic peptides are regularly purified by RPHPLC (Figure 55), although other techniques are also used, such as cation exchange,[161,743,744] mixed-mode HIC/cation exchange,[224,647–649] ion pair chromatography,[745] and IMAC,[495] specifically for isolating peptides with metal-binding N-terminal amino acids (His, Trp, or Cys).[746] The conventional eluent for RPHPLC of peptides is an aqueous acetonitrile gradient acidified with TFA. Addition of perchlorate ions to the mobile phase was recently demonstrated by Sereda et al.[236] to have a pronounced effect on the retention of synthetic amphiphilic α-helical and nonhelical peptides in C_8 RPHPLC, where phosphoric acid was used to acidify an acetonitrile gradient. The general trend seen on adding perchlorate was an increased retention, accompanied by changes in selectivity. These effects were ascribed to ion-pair formation between amino acids with a positively charged side-chain and the perchlorate ions, which was also confirmed by calculations. The selectivity of the eluent containing

Figure 55 Gradient RPHPLC chromatogram of the peptide-enriched fraction obtained from one human pituitary. The arrows indicate the retention time of synthetic peptides, and the brackets indicate collected peptide fractions. (Reproduced from D.M. Desiderio, *Anal. Chim. Acta*, **352**, 89 (1997) by permission of Elsevier Science B.V.)

aqueous phosphoric acid–perchlorate–acetonitrile was also markedly different from aqueous acetonitrile–TFA. Addition of chaotropic anions to the eluent thus provides a tool for altering the retention compared to that obtained with acetonitrile–TFA gradients. Chiral separations[211,691] may be required for determination of the enantiomeric purity of peptides in the pharmaceutical, alimentary, and agricultural industry.

An entire volume of *Analytica Chimica Acta* was recently devoted to the chromatography of peptides. Among the reviews presented was a survey by Štulik et al. of RP, HIC, SEC, IEC, affinity, and CSP for peptide analysis by HPLC.[95] The paper contains an outline of how the chromatographic behavior of a peptide is influenced by its physicochemical properties and lists a number of manufacturers providing columns with different chemistries for separation of peptides. Characterization and purification of peptides by high-performance strong cation-exchange chromatography was reviewed by Crimmins.[569] A commonly used stationary phase is sulfoethyl aspartamide. Separations are carried out at an acidic pH to promote the cationic character of basic groups. Among the synthetic analytes used as examples are N-terminally blocked and disulfide linked peptides. Separation of model peptides subjected to limited proteolysis was reviewed by Rholam and Cohen,[747] with particular emphasis on cleaving site structure in order to establish models for peptide hormone catabolism. Monitoring proline-specific endo- and exo-peptidase activity by HPLC assays was reviewed by Harada.[234] Characterization of human hemoglobins by the differences in their polypeptide chains was reviewed by Huisman,[748] discussing separations by cation exchange and RPHPLC on short alkyl chain columns. Meriluoto[235] summarized the separation of microcystins and nodularins, classes of cyclic

hepatotoxic peptides with tumor-promoting properties produced by water-blooming cyanobacteria. Emphasis is placed on the conditions for extraction from different types of sample matrices, separation by anion exchange, and by RPHPLC with conventional and internal surface materials. A comparison is also made with other methods for determination of these peptides. A strategy for screening of combinatorial peptide libraries was reviewed by Hammond,[238] focusing on peptide sequences immobilized on a carrier and used as affinity ligands in highly specific purification schemes for proteins. The interaction of the target amino acid sequence FLLVPL with fibrinogen (blood clotting Factor I) was described and its use for purification of the protein was discussed.

Neuropeptide separation has been treated in several recent reviews. Rissler[749] addressed sample preparation, separation, and determination of low levels of peptides related to substance P, an undecapeptide involved in the transmission of pain. Hurst and Zagon[750] reviewed the sample preparation, separation and detection of enkephalins. Desiderio presented a review of separation and detection of endogenous neuropeptides[237] in various biological tissues and fluids, and Desiderio and Zhu[239] reviewed the sample collection, SPE clean-up and HPLC separation in the determination of Met-enkephalin and β-endorphin from pituitary gland tissue (Figure 55). Both papers discussed radioimmunoassay (RIA) and tandem MS, among other detection techniques, and concluded that tandem mass spectrometry (MS/MS) was superior for detecting these peptides.

Multidimensional separations are required to separate highly complex peptide mixtures. An LC/LC/MS system for mapping fragments from proteolytic digests was thus constructed by Jorgenson et al.,[192] based on conventional diameter analytical HPLC columns. The first separation dimension was by SEC, using six 30-cm long columns in series with 0.1% aqueous TFA as the mobile phase. Fractions from this column train were transferred to an RPHPLC separation step using two columns packed with nonporous C_{18} modified silica with an aqueous acetonitrile gradient containing 0.05% TFA (Figure 56). Peptide fragments from ovalbumin and BSA were separated with this system and identified by electrospray MS. Another LC/LC/MS technique (cation exchange followed by RP) was also found to be promising for the separation and identification of undigested proteins.[751]

Coupling HPLC with electrophoretic separation techniques adds yet another separation dimension because of the radically different separation principle of CE compared to interaction chromatography. Moore and Jorgenson separated fluorescein isothiocyanate (FITC)-tagged peptide fragments from trypsin digests of hen

Figure 56 Single coupled-column RPHPLC chromatogram extracted from a SEC separation (retention time interval 90–94 min), showing separation of tryptic peptides as detected at 215 nm. (Reproduced from G.J. Opticek et al., *Anal. Chem.*, **69**, 2287 (1997) by permission of American Chemical Society.)

ovalbumin by size exclusion on a hydrophilic macroporous 2-hydroxyethyl methacrylate/ethylene dimethacrylate (HEMA/EDMA) copolymer column, using 85% methanol–100 mM ammonium acetate as mobile phase at low flow rates. The fragments eluted from the SEC column were sampled repetitively on-line and subjected to separation on a narrow bore 5-μm C_8 column with a fast aqueous acetonitrile gradient. The exit of this column was in turn linked to a vertical fused-silica CZE capillary, onto which sampling was triggered by a high speed optical gating injection system to obtain a comprehensive three-dimensional peptide separation.[752,753] Another automated application of HPLC is in the chromatography-based assay of enzyme activities, reviewed by Lambeth and Muhonen.[754] The potential of multiple separation techniques in combination with selective and sensitive detection is large, but the design and operation of multi-dimensional systems requires considerable expertise and it is not yet a feasible technique for most analytical laboratories. It should also be mentioned that matrix-assisted laser desorption/ionization (MALDI) and direct injection electrospray MS are nonchromatographic separation techniques that can be favorably used for peptide samples in relatively sparse matrices.[755]

Detection-oriented techniques for identification and determination of peptides containing arginine, cysteine, proline, tryptophan, or tyrosine residues were reviewed by Cui et al.[756] A number of selective derivatization reagents were discussed, targeting each residue, and electrochemical (tyrosine-containing peptides), UV, and fluorimetric detection is used to identify the residues based on the properties introduced by the reagents.

8.3 Proteins

Chromatographic separation of proteins can take place either by interaction or by size exclusion. Interaction chromatography is based on contact between the amino acid residues at the outer surface of the protein and the stationary phase, resulting in interactions whose strength is adjusted by varying the mobile phase conditions. Proteins differ in stability and their conformation can be significantly altered during separation, with changes in their surface properties as result. Which residues will be exposed is of course determined by the basic structural features of the protein, but also to a large extent by the chromatographic conditions. The factors important for controlling the protein structure and hence the exposed surfaces during separation are the stationary phase (the nature of the ligands and their density, the chemical nature and porous properties of the matrix), the mobile phase composition (pH, solvents, concentration and type of added salts or nonionic agents affecting the water structure, presence of detergents or other additives), and also physical factors (temperature and flow rate). A general strategy for the separation of proteins is therefore difficult to formulate.[99]

The best guidance is obtained by gathering as much information as possible on the proteins to be separated. Amino acid sequence, chemical nature, size, helicity and three-dimensional structure, and knowledge of the biological function are factors that can be useful in selecting an optimal separation scheme. If the proteins have been characterized, data are likely to be present in databases that are freely available on the Internet. One such database, which is referenced here in spite of the volatile nature of the Internet, is the ExPaSy Molecular Biology Server.[576] The data that can be collected or computed on this server can be very useful for designing protein separations. Among the modules available is a huge database of protein sequences, families and domains, two-dimensional polyacrylamide gel electrophoresis data, three-dimensional images of proteins and other biological macromolecules, and enzyme nomenclature. Tools for protein identification and characterization, facilities for similarity, pattern and profile searches, primary structure analysis and secondary structure prediction, and tertiary structure and transmembrane region detection also exist on this server. Calculations can be done from the database entries, or from user-entered primary structures. ExPaSy also provides links to a large number of other servers with additional databases and computational facilities.

Advanced protein separation techniques was the topic of a recent review issue of *Journal of Chromatography*, including overviews of new packing materials,[96] nonporous sorbents,[97] permeable packings,[98] and protein interactions at sorbent interfaces.[757] Strategies were reviewed for separation of recombinant proteins,[758] sensitive enzymes,[86] modified hemoglobins,[759] lipoproteins,[611] glycoproteins,[760] glycated and carbonylated proteins,[319] and the isolation of allergens.[761] Special techniques such as labeling reactions[688] and the studies of drug–protein interactions[762] were also part of this issue. A number of books are also devoted to chromatography of proteins.[51,73,737,738,763–766] A recent monograph by Sadana[767] deals with the mechanisms for different bioseparation processes and how they affect protein stability. The molecular basis of surface activity and protein adsorption is discussed and strategies for avoiding inactivation are outlined. Oscarsson[757] has reviewed the factors leading to partitioning of biomacromolecules to sorbents, with particular attention to protein–surface interactions, and describes a scanning probe microscopy technique for studying such interactions at the nanometer level. Beeckmans[768] has reviewed the use of chromatographic techniques for studying protein–protein interactions, and provides an extensive practical section on support activation and immobilization.

8.3.1 Membrane Proteins

The group of proteins associated with cellular membranes differ in their way of attaching to the lipid bilayer. Integral membrane proteins are attached either by covalently bound lipid chains, or by having a consecutive sequence of amino acids with low-polarity side-chains sufficiently long to extend through the lipid membrane, whereas the extrinsic membrane proteins are associated with these proteins, or the head groups of the bilayer lipids. The salient amphiphaticity makes it difficult to detach integral proteins from the lipid membrane, and the use of detergents is necessary in order to solubilize the membrane and get the proteins into solution. The difficulty of finding appropriate conditions increases with the number of components in the system, and a series of different steps are often needed in order to prepare injectable samples of the different proteinaceous components of membranes. Strategies for finding these conditions, as well as choosing separation technique and detergents, are outlined by Josic et al.[769,770] Tools for predicting transmembrane regions in a protein are available through the ExPaSy server[576] and might be useful in method development.

Once the proteins have been solubilized, they are amenable to separation by practically the entire array of separation chemistries applicable to proteins. There are some particular problems that should be kept in mind, such as microheterogeneity due to differences in glycosylation pattern, irreversible adsorption to the column due to nonspecific interaction, the tendencies to precipitate or aggregate, and the strain put on the system because of the high concentrations of salt, detergents, or other denaturing reagents that may have to be added to the eluents to overcome these tendencies. Subject to the nature of the protein, mild detergents can be sufficient to suppress aggregation and precipitation, in which case separation can be made under nondenaturing conditions with IEC, hydroxyapatite, HIC, and various affinity chemistries. Otherwise, or if the selected separation chemistries are SEC and RPHPLC, the addition of strong, denaturing detergents, urea, or other denaturing agents is normally necessary. Solubilizing detergents also tend to dynamically modify the stationary phase by adsorption, leading to substantial changes in interaction patterns.[769] Lundahl et al.[771] evaluated hydroxyapatite columns of different brands for separation of integral membrane proteins solubilized in SDS (sodium dodecyl sulfate) and found considerable differences in elution pattern (Figure 57).

von Jagow and Schgger have presented a monograph devoted entirely to practical aspects of membrane protein purification.[764] An interesting ancillary development that should be mentioned in connection with membrane proteins is the use of immobilized liposomes, proteoliposomes, or biomembranes for studies of interactions of proteins with lipid surfaces.[6,414]

Figure 57 Chromatograms of solubilized human erythrocyte integral (intrinsic) membrane proteins in complex with SDS using hydroxyapatite HPLC columns of four different manufacturers: (A) Tonen Taps-020810, (B) PENTAX SH-0710F, (C) A-7610 and (D) TSKgel HA-1000. The SDS–polypeptide complexes (0.5 mg) were eluted with a phosphate buffer concentration gradient at a flow rate of 0.8 mL min^{-1}. The height of each panel corresponds to 0.12 absorbance units at 280 nm. Arrows indicate fractions that were analyzed by electrophoresis. Conductivities of 10, 20 and 30 mS cm^{-1} at 25 °C correspond to phosphate concentrations in the eluent of 85, 205, and 370 mM, respectively. (Reproduced from P. Lundahl et al., *J. Chromatogr.*, **604**, 98 (1992) by permission of Elsevier Science B.V.)

8.3.2 Lipoproteins

Serum LPs are complexes between proteins and lipids found in blood serum. The core consists of hydrophobic components such as triglycerides or cholesterol esters, shielded by an amphiphilic layer that is comprised mainly of proteins (Figure 58).

Figure 58 Diagram of an LP particle. (Reproduced from T. Takey, W.C. Purdy, *J. Chromatogr. B*, **671**, 238 (1995) by permission of Elsevier Science B.V.)

LPs are classified as high-density lipoproteins (HDLs), low-density lipoproteins (LDLs), and very-low-density lipoproteins (VLDLs), determined by the relative buoyancy in a tedious, complicated, and time-consuming gradient ultracentrifugation process. Takey and Purdy[772] reviewed preparative and analytical separations of LPs, using SEC, affinity chromatography, and HPLC techniques for resolution of structurally different LPs. A review of separation strategies for LPs was also recently presented by Shibusawa,[611] who concluded that the preferred separation technique for HPLC of LPs is hydroxyapatite chromatography with step changes in phosphate concentration at pH 7.4 for elution (Figure 59). This technique can separate all three classes of LPs, but is unable to resolve HDLs from serum albumin and globulin. A complementary technique is CCC, which offers the very mild separation conditions required to preserve the structures of the aggregates during separation. Combined use of these two techniques with CCC as a preliminary fractionation step for final separation by hydroxyapatite chromatography is capable of resolving all three classes of LP.[611] Note that CCC is not an HPLC technique, and it requires highly specialized and quite complicated equipment.

8.3.3 Recombinant Proteins

Proteins expressed in prokaryotic organisms impose particular challenges on chromatographic separations for purification and analytical purposes. Glycosidation patterns of recombinant proteins are often different from proteins expressed in eukaryotic systems, protein folding is an issue, and the extraction of proteins that are excreted by eukaryotic cells but remain inside prokaryote organisms may call for rigorous conditions

Figure 59 Stepwise elution profile of human serum LPs on a Bio-Gel HTP DNA grade hydroxyapatite column (250×10 mm i.d.) using 25, 200, 300, and 650 mM potassium phosphate buffer at pH 7.4 as eluents in a step gradient fashion, at a flow rate of 0.2 mL min^{-1}. Sample: 2.0 mL human serum. (Reproduced from Y. Shibusawa, *J. Chromatogr. B*, **699**, 427 (1997) by permission of Elsevier Science B.V.)

for solubilization or separation[773,774] of inclusion bodies. The use of column chromatography for the purification of recombinant proteins was reviewed by Jungbauer and Boschetti[775] with special emphasis on validation and on long-term stability in the chromatographic separation processes. Evangelista Dyr and Suttnar[758] reviewed methodologies applicable to the purification of recombinant proteins, including sample preparation and assays methods, and compared the techniques with those used in the purification of conventional proteins.

A correct disulfide bonding pattern is central for folding of recombinant proteins and verification of correct disulfide linkages should therefore be part of the quality control scheme for recombinant proteins. Lei et al.[776] described the use of tryptic mapping of recombinant human growth hormone on an immobilized enzyme cartridge, followed by on-line separation of fragments by TFA/acetonitrile RPHPLC (Figure 60). The MALDI/TOFMS technique was used to verify the absence of peptides with mismatched disulfide bridges. Ikegaya et al.[777] used the Edman degradation and pepsin mapping followed by HPLC on C_{18} columns to elucidate the exact positions of the disulfide bridges in a purified recombinant HSA. General characterization of recombinant proteins is often performed with CE instead of by HPLC.[778,779]

8.3.4 Enzymes

In analytical separations of biomolecules, it is often sufficient to establish stable and reproducible conditions so that the molecule under study elutes as a single well-shaped peak at a predictable retention time, separated from other biomacromolecular components of the sample. Denaturation and loss of biological activity that accompanies conformation changes is therefore often an intentional part of the sample preparation. It may also be induced by the choice of mobile phase components or stationary phases that lead to controlled denaturation. Enzymes are different, because the purpose of a separation is typically to recover the enzyme in its native state with maintained biological activity, in particular in preparative high-performance separations. The in vitro stability of enzymes varies, with some being quite unstable. Special techniques are therefore often required when the goal of the separation is to preserve biological activity, a topic addressed in a review by Kaufmann.[86] Among the techniques advocated are perfusion chromatography and the use of tentacle gels,[163] to accomplish fast chromatography on soft interaction media.

Toribio et al.[780] have reviewed recently developed protocols for the purification of pyridine nucleotide-dependent enzymes. All of the referred protocols made use of chromatographic steps, with affinity

Figure 60 Tryptic map of (a) native and (b) reduced recombinant human growth hormone. The protocol and conditions for reduction, digestion, and RP chromatography are found in the original paper. Labels refer to tryptic fragments; lower case letters correspond to incomplete tryptic digests and peaks marked with an asterisk correspond to unreduced disulfide bridged fragments. (Reproduced from J. Lei et al., *J. Chromatogr. A*, **808**, 125, 127 (1998) by permission of Elsevier Science B.V.)

chromatography being employed in more than nine out of ten occasions. Among the ligands used were Cibacron Blue F3GA, Procion Red HE3b, Orange A, and 2′,5′-ADP. Frequently encountered were also IEC, SEC and HIC, whereas other chromatographic modes were used more sporadically. The sequence in which the chromatographic steps are performed is important to make best use of the separation dimension and sample capacity offered by each technique, leading to rather complicated schemes like the one outlined in Figure 61. The authors recommended the use of perfusion sorbents and also considered the development of tailor-made molecularly imprinted stationary phases specific for individual enzymes as a goal for the future. Toribio et al. have also reviewed purification techniques for glutathione-related enzymes (reductase, peroxidase and transferase).[171] The hegemony of chromatography for preparative purposes was demonstrated by its utility in all of the reviewed papers, whereas only 3% of the procedures used preparative techniques based on electrophoresis or isoelectric focusing. The need to utilize more than one separation dimension in an overall purification scheme was obvious – two or more chromatographic techniques with different selectivities were used in more than 90% of the protocols, and in more than half of the protocols three or more chromatographic dimensions were used.

The purification of carbonic anhydrase isozymes from different sources was reviewed by Bergenhem,[781] with emphasis on application of their sulfonamide complexes in single-step affinity schemes. Kopperschläger and Kirchberger[782] reviewed methods for the separation of LDH and its isoforms, concentrating on affinity separation techniques using natural and pseudo-biospecific ligands. Methods for the separation of superoxide dismutase isoenzymes were reviewed by Michalski[783] along with techniques for monitoring their purification and measuring their activity. Lin et al.[784] provided an overview of methods for the purification of hydroxysteroid dehydrogenases, mainly by HIC and dye-affinity chromatography. Sample preparation, prefractionation, and separation techniques for mammalian cytochrome enzymes based on IEC, hydroxyapatite, HIC, and immobilized metal affinity systems were reviewed by Roos.[785] Multistep separations using SEC, IEC, hydroxyapatite chromatography, and RPHPLC for the isolation and characterization of mammalian catechol-*O*-methyltransferase were reviewed by Tilgmann and Ulmanen.[786] A wide array of chromatographic techniques (RPHPLC, IEC, HIC, TAC, and affinity schemes based on sorbents with phenylboronate, immobilized metal ions, and cyclodextrin and starch as biospecific ligands) applicable to the separation of α- and β-amylases and their isoenzymes from complex extracts was reviewed by Brena et al.,[320] Moriyama and Ikeda[787] reviewed the assay of clinically relevant amylase enzymes, acting on glycosidic bonds.

The purification of proteases using HIC and affinity schemes with cyclic peptide antibiotics and immobilized dyestuffs as protease-specific ligands was reviewed by Ibrahim-Granet and Bertrand.[788] Hamada[789] reviewed the use of preparative HPLC for the large-scale production of carbohydrate hydrolases, proteases, and transglutaminases from food, microbial and plant sources for industrial applications. Parmentier et al.[790] reviewed the purification of glutathione synthetase, glutathione reductase, γ-glutamylcysteine synthetase, and γ-glutamyltranspeptidase by the use of multiple LC separations. Isolation of transglutaminase isoforms from tissue and body fluids along with procedures for purification of γ-glutamyltransferases were reviewed by Wilhelm

Figure 61 General purification scheme suitable for $NADP^+$-dependent enzymes according to Toribio et al.[780] (Reproduced from *J. Chromatogr. B*, **684**, 2 (1996) by permission of Elsevier Science B.V.)

et al.,[791] particularly addressing the problems caused by formation of irreversible aggregates. The most widely used separation techniques were SEC and IEC. Affinity schemes based on heparin for the purification of lipases, phospholipases, and kinases were reviewed by Farooqui et al.[448] Focus was also placed on techniques for attaching heparin to supports and detecting its presence after immobilization. Raspi[792] presented a review of sample preparation, purification, and assays for isolating and determining kallikrein proteinases from tissues and body fluids. Knudsen et al.[793] reviewed chromatographic and electrophoretic separation strategies for eukaryotic DNA topoisomerases isoforms, and the techniques used for determining their catalytic activity. The added benefit of high-sensitivity metal analysis by coupling a separation of metal-containing enzymes to inductively coupled plasma mass spectrometry (ICPMS)[794] is illustrated in Figure 62.

The availability of assay techniques is central for determining the biological activity of enzymes during and after isolation. Many such assays are based on HPLC, and a few overviews covering different HPLC assays have appeared in the recent literature.[754,795–797]

8.3.5 Protein Folding and Unfolding Studies using High-performance Liquid Chromatography

By virtue of the large variations in surface properties and the possibility of controlling the interaction time and strength by manipulating the eluent parameters, liquid chromatographic techniques lend themselves to studies of protein folding and unfolding, the processes responsible for denaturation and irreversible adsorption of proteins on sorbent interfaces. Modulation of the hydrophobicity of polymethacrylate coatings on porous and nonporous silica enabled Hanson et al.[142] to mediate selective unfolding of proteins on the sorbent surface, conformational changes that made it possible to alter the separation pattern of the protein probes lysozyme, cytochrome *c*, and myoglobin. Similar effects were seen for synthetic peptides with defined secondary, tertiary, and quaternary structures.[143] Benedek[798] studied the unfolding

Figure 62 Size-exclusion HPLC and metal ion determination of an alanyl-aminopeptidase from *Pseudomonas aeruginosa*: (a) UV detection at 254 nm; (b) corresponding chromatogram using ICPMS detection showing distribution of Zn and Ca. (Reproduced from I. Leopold, B. Fricke, *Anal. Biochem.*, **252**, 284 (1997) by permission of Academic Press.)

of recombinant human brain-derived neurotrophic factor on butyl columns by varying the temperature and incubation time in acidic RP eluents, and found that the data supported a process wherein the dimeric protein is first attached to the surface, then dissociated into its monomeric units, which are subsequently unfolded. The unfolding mechanisms were different in acetonitrile and 1-propanol eluents. Purcell et al.[799] used peptides as probes with butyl and octadecyl RP stationary phases over a wide range of temperatures, and found that the bandwidth could be correlated with secondary structure and dynamics of conformational changes. Richards et al.[277] studied the retention behavior and conformational states of cytochrome *c* of different origin in RPHPLC on C_4 and C_{18} columns by using aqueous TFA/acetonitrile eluents at different gradient times and elution temperatures. In a simultaneously published work, the same group[800] made use of variations in the 4σ bandwidths of the eluted peaks to study how the secondary and tertiary structures contributed to the interaction of these proteins with the stationary phases.

Hodges et al.[801] correlated the retention differences of two synthetic amphiphatic α-helical peptides differing in three residues (valine and isovaline, respectively) and on a C_8 column with CD measurements of their helical stability. A study on how the recoveries of albumin, fibrinogen, and IgG varied with the time the proteins were allowed to be in contact with nonporous strong anion and cation-exchange materials was done by Goheen and Hilsenbeck,[570] by adjusting the salt gradient steepness. They found that recoveries were correlated to the residence times and ascribed their results to an initial weak binding followed by a stronger attachment, whose time dependence is due to the time required by the protein to unfold on the charged surface (Figure 63). Related to the area of protein folding is also the studies of chaperonins, proteins that assist in or accelerate protein folding and prevent aggregation, the purification of which was recently reviewed by Quaite-Randall and Joachimiak.[802]

8.4 Carbohydrates and their Conjugates

Polysaccharides play very important and highly diverse roles in biological systems, ranging from basic energy

Figure 63 Protein recovery with time on a quaternary amine support. Proteins were introduced individually to the column under the conditions of pH 7.4, 37 °C, and a flow rate of 1.0 mL min^{-1}. Recoveries were determined from peak areas by their absorbance measured at 280 nm. Residence times were varied by either prolonging the gradient time (from 0 to 1 M NaCl in 5 mM TRIS) or maintaining the [NaCl] = 0 condition for various periods of time. Both methods produced similar results. (Reproduced from S.C. Goheen, J.L. Hilsenbeck, *J. Chromatogr. A*, **816**, 92 (1998) by permission of Elsevier Science B.V.)

storage, over structurally reinforcing and impact-damping elements, to complex signaling and recognition systems. Furthermore, biologically derived carbohydrate macromolecules have a large economic importance in industry, as rheological modifiers in the food and cosmetic sectors, and as a basis for the paper pulping and the vegetal fiber textile industries. Process and quality control in these industries calls for ways of isolating and characterizing polysaccharides, which are often of very high molecular weight, with respect to differences in composition, branching, and charge. Polynucleotides are, although treated separately here, in principle also carbohydrate polymers, although their pendant nucleotide bases provide other possibilities for separation. In other areas of the bioscience, substantial interest is presently devoted to glycoconjugates of polypeptides and lipids. Their characterization requires techniques for separating relatively small polysaccharides cleaved from the conjugates, and also of smaller oligosaccharide fragments and single monosaccharides after enzymatic cleavage. The differences sought in these compounds are often subtle and highly demanding on the separation chemistry. Techniques used for studies of carbohydrates are consequently highly diverse.

The basic property of polymeric carbohydrates is their monomeric structure, i.e. the kind and sequence of sugars incorporated. Branching is also central, as is charge derived from the presence of carboxylic groups, sulfate moieties, or amino groups on the sugars. When the polysaccharide reaches a certain length, these properties will have a large impact on its behavior and also its HPLC separability. Very large polysaccharides are almost exclusively separated by HPSEC, and the first problem facing the analyst is to ascertain that the sample is properly dissolved, and that the association between chains is minimal in the separation solvent. Most large polysaccharides will dissolve in water and can be separated in aqueous eluents, although both the dissolution and separation will often require heating to overcome associations that manifest in gelation behavior. Although silica can be used for the separation of many carbohydrates, it will not withstand elevated temperatures over a long time. Polymeric stationary phases are therefore preferred. Solute dissolution usually takes place quite readily when the polysaccharides are charged or highly branched, whereas uncharged polysaccharides with little or no branching form crystalline structures that require more vigorous conditions for dissolving and keeping the polymers from aggregating in solution. For example, cellulose and chitin take several days to dissolve by swelling in *N*,*N*-dimethylacetamide/LiCl. This is the only solvent system known to dissolve underivatized cellulose, and is also used in the HPSEC separation[803] (Figure 64).

Figure 64 Size-exclusion chromatographic (a) mass fraction and (b) cumulative M_r distribution plots for cellulose linters powder dissolved in the LiCl/DMAC solvent system. (Reproduced from M. Strlic et al., *J. Chromatogr. A*, **805**, 96 (1998) by permission of Elsevier Science B.V.)

Another problem in SEC of high-M_W charged polysaccharides is their high intrinsic viscosity, caused by their expanded configuration in solution. Macromolecular crowding will occur if the injected concentrations are too high in a SEC separation, due to entanglement of the polymers chains approaching the pore system. This solute-induced restricted access to the pore space produces peak distortions, which effectively maximizes the sample concentration. For very high molecular weights the maximum acceptable concentration can be as low as 0.02%. With injected concentrations this low detection becomes difficult, augmented by the absence of natural chromophores in polysaccharides. Introduction of a detectable group, such as a fluorescent group, onto high-molecular-weight polysaccharides by derivatization has yielded only limited success, because the labeling becomes less efficient as the molecular size increases.[805] Molecular weight calibration of polysaccharides in SEC is furthermore a source of concern. The shape factors of polysaccharides vary quite strongly, so different polysaccharide molecular weight standards are not directly interchangeable. Pullulans and dextrans can be acceptable as calibration standards for compounds with similar solution behavior, but a better alternative to external calibration is to use a MALLS detector (see above), or a combination of some other scattering and viscosity measurements, to determine the molecular weight on-line. Carbohydrate separation by SEC, including considerations for selection of columns, has been reviewed by Churms.[806]

More separation options are available for oligosaccharides and smaller polysaccharides. Although sugars are very polar, RPHPLC of uncharged oligosaccharides is possible on regular alkylsilane columns. However, the retention for underivatized oligosaccharides is so low that almost totally aqueous eluents have to be used,

Figure 65 Reversed-phase separation of positional isomers of dimaltosyl-β-cyclodextrin on (a) a YMC-Pack A-312 ODS column with methanol–water (6 : 94) at 35 °C and (b) a Hypercarb with acetonitrile–water (17 : 83) at 50 °C. Peaks: $1 = 6^1$, 6^3-, $2 = 6^1$, 6^4-, and $3 = 6^1$, 6^2-di-*O*-(α-maltosyl)-β-cyclocextrin. Flow rate 1 mL min^{-1}. RI detection. (Reproduced from K. Koizumi, *J. Chromatogr. A*, **720**, 124 (1996) by permission of Elsevier Science B.V.)

conditions that are known to result in phase collapse and eventual expulsion of eluent from the pore system. The bonded phase density also has a profound effect on retention, as does the presence of uncapped silanol groups.[227] Dissociation of carboxylic carbohydrates such as pectin and its fragments can be suppressed by the use of acidic eluents.[807] The retention for acidic carbohydrates can be increased by formation of ion pairs[232] with cationic tetraalkylammonium ions, in a process that can be regarded either as the result of partitioning of hydrophobic ion pairs formed in the liquid phase, or a dynamic coating of hydrophobic cations onto the RP sorbent, effectively transferring it into a cation-exchange sorbent. Porous graphitized carbon (PGC) offers separation according to the RP principle. The retention is higher compared to alkylsilane columns and the PGC columns have a more pronounced selectivity, which appears to be substantially influenced by the solute shape. The resolution of anomeric forms and closely related oligosaccharides is therefore possible,[808] as illustrated in Figure 65.

Of opposed selectivity to RPHPLC is HILIC, practiced on polar stationary phases with aqueous eluents containing relatively high concentrations organic solvent, typically acetonitrile. A wide variety of stationary phases have been used for HILIC separation of diverse carbohydrates, ranging from monosaccharides to relatively large sialic and asialic oligosaccharides. The retention shows a marked influence on the nature and position of sugar units, and HILIC is therefore valuable in separations of hetero-oligosaccharides, exemplified by an ability to separate recombinant human interferon-γ based on site-specific glycosylation microheterogeneity (Figure 66). The use of HILIC for separation of carbohydrates has been reviewed.[220]

Classical anion-exchange chromatography has been used for a long time in the separation of carbohydrates.

Figure 66 A HILIC chromatogram of tryptic glycopeptides of Asn^{25} from recombinate human interferon-γ on a polyhydroxyethyl aspartamide column (150 × 1 mm i.d.). The glycopeptide fractions from a preceding RP separation step were mixed with mobile phase A (85% acetonitrile, 15% water, 10 mM triethylamine; pH 6.0) and then loaded onto the HILIC column at 0.1 mL min^{-1}. Gradient elution: 50 μL min^{-1} with a 60-min gradient from 100% mobile phase A to 100% mobile phase B (20% acetonitrile, 80% water, 10 mM triethylamine, 25 mM $NaClO_4$; pH 6.0). Detection: UV, 220 nm. Manually collected fractions were identified by MALDI/TOFMS. (Reproduced from J. Zhang, D.I.C. Wang, *J. Chromatogr. B*, **712**, 77 (1998) by permission of Elsevier Science B.V.)

The anionic properties of sialic carbohydrates provide for direct separation, but neutral carbohydrates need to be complexed by borate to form anionic species that are retained on anion-exchange resins. This technique is now largely obsoleted by high-pH anion-exchange chromatography (HPAEC) using strongly alkaline eluents to promote a dissociation of the carbohydrate hydroxyls, so that neutral sugars are converted into anionic species.[596] Thus, HPAEC is applicable to both sialic and asialic oligosaccharides without the need to add a separate complexing agent. Hydroxide ion is a weak eluent, so solutes are eluted from the column by an increasing concentration of a pushing ion, typically acetate or nitrate (Figure 67). The retention is largely a function of the number of hydroxyl groups, corresponding to the degree of polymerization. Obviously, high-pH eluents necessitate the use of hydrolysis-stable polymeric columns. An advantage of the alkaline eluent is that the separated sample can be detected by a PAD detector (see above) without postcolumn addition of base. The disadvantages of high-pH eluents are epimerization and degradation of the samples, to which there is no good solution. Still, HPAEC has secured a central position among modern HPLC techniques for oligosaccharide separation. Sialylated oligosaccharides can be separated from asialics by elution at a lower pH, although base must then be added to enable detection by PAD. The HPAEC technique has been reviewed by Lee.[567] Hydroxyapatite is also an ionic separation mode applicable to the separation of glycosaminoglycans.[615]

Affinity chromatography of carbohydrates is possible either through the formation of cyclic boronate esters with aminophenylboronic affinity phases, which is a technique particularly valuable for sample work-up and enrichment, or by the use of immobilized lectins[437] (see affinity section). Glycoaffinity chromatography and its applications in studies of biological recognition has been reviewed by Caron et al.[811]

Absence of detectable groups is a concern not only for high-molecular-weight carbohydrates, as outlined above. Saturated carbohydrates absorb light only at very low UV wavelengths, where the chemical noise from other sample compounds and solvent contamination becomes problematic. Monounsaturated sugars produced by enzymatic cleavage have their absorption wavelength somewhat shifted, but still in the low UV. Derivatization reactions aimed an enhancing the detectability of oligo- and polysaccharides have therefore been employed for many years. Derivatization could aim at any of the polar groups in polysaccharides, but this is not practical for several reasons, except in GC and SEC where the purpose is to reduce the polarity of sugars and oligosaccharides.

Figure 67 Separation of Neu5Ac oligo/polymers derived from colominic acid (equivalent to 100 μg) on a CarboPac PA-100 column using an eluent containing 0.1 M NaOH with a superimposed 1 M $NaNO_3$ (E1) gradient, as indicated in the figure. Detection was by pulsed amperometry, using a gold working electrode. The inset shows an enlarged view of the retention time interval between 61 and 74 min. Peaks are labeled with degree of polymerization. (Reproduced from Y. Zhang et al., *Anal. Biochem.*, **250**, 247 (1997) by permission of Academic Press.)

Instead the reducing end of the polysaccharide is targeted,[812] which is also used to deal with a separation problem in interactive chromatography of small sugars, namely the splitting of α- and β-anomers and their on-column isomerization leading to badly shaped double peaks.[813] This can be eliminated by derivatization schemes using reductive amination (see Figure 68). Introduction of a nonpolar group in the terminal end of the oligosaccharide also has a positive effect by increasing the interaction with RP sorbents. Postcolumn derivatization as a means of modifying carbohydrates for spectrophotometric, fluorimetric, or electrochemical detection in HPLC has been reviewed by Honda.[814]

In glycosylated proteins, the borderline between a protein and a polysaccharide is diffuse, indicated by their

Figure 68 Normal-phase HILIC chromatography of oligosaccharides in human milk derivatized by reductive amination with 2-aminoacridone on a GlycoSep N column (250 × 3.9 mm i.d.): (a) blood group O, (b) blood group A, and (c) blood group O. Mobile phases: A, acetonitrile; B, 250 mM ammonium formate, pH 4.4. Gradient: 20–58% B over 152 min. Fluorescence detection at 428/525 nm. (Reproduced from J. Charlwood et al., *Anal. Biochem.*, **273**, 275 (1999) by permission of Academic Press.)

nomenclature. Glycoproteins comprise anywhere from 1% to 80% of their weight as oligo- and polysaccharides attached to their surfaces, which should intuitively lead to a substantial change in their interaction patterns. The influence of this carbohydrate modification is surprisingly low, however, and glycoproteins are therefore isolated on the basis of their protein properties (charge and hydrophobicity), rather than on the basis of their carbohydrate properties.[227] Affinity chromatographic schemes,[760] hydroxyapatite chromatography[816] (Figure 69), or CE[817] are useful when glycosylation pattern heterogeneities are sought. The use of HPAEC for separation of glycopeptides obtained in tryptic maps was recently review by Townsend et al.[818] Proteoglycans, which have a protein core – usually a glycoprotein – may contain up to 95% oligo- and polysaccharides[819] of 200 or more disaccharide units, and reach molecular weights in excess of 1 MDa.[820] Their extraction from tissue requires special consideration and separation is mostly carried out on SEC or nonHPLC techniques.[820] Glycosaminoglucans (GAGs) – the oligosaccharide chains of proteoglycans – are composed of alternating uronic acid and *N*-acetylhexosamine residues, which give the molecules a net negative charge, augmented by sulfate groups attached to hydroxyls. According to Alberts et al.,[819] these oligosaccharides have an almost limitless heterogeneity potential, which obviously makes chromatographic separations and other means of characterization difficult. The complicated biochemical pathways involved in the biosynthesis of oligo- and polysaccharides attached to lipids and proteins are indicators of their important function, but most of these biological functions are still not known.[821] Glycobiology is consequently an important and growing area in molecular biology, dealing with elucidation of the cellular functions of glycoconjugates. The first steps in this work is to characterize the carbohydrate moieties. Although modern MS techniques have evolved into extremely powerful tools for glycobiology,[822] the complexity of carbohydrates and their conjugates still calls for a battery of separation and detection steps coupled with chemical and biological modifications to accomplish the most complicated characterizations. The use of CZE[823,824] and supercritical fluid chromatography[825] has been reviewed and is not covered here.

Characterization of oligosaccharides conjugated to other biomolecules requires that they are detached from their protein, peptide, or lipid components, a feat nowadays accomplished by enzymes. Prior to cleaving the carbohydrate portion from glycoproteins, these are usually broken down into peptides by proteases, so that steric hindrance in the enzymatic detachment is minimized. Detachment of N-linked oligosaccharides is feasible by several enzymes, either at the

Figure 69 Chromatogram of the glycoforms of α_1-acid glycoprotein from the serum of healthy subjects separated by high-performance hydroxyapatite chromatography. For conditions, see inset. (Reproduced from S. Kishino et al., *J. Chromatogr. B*, **703**, 3 (1997) by permission of Elsevier Science B.V.)

Asn linkage by glycosamidase resulting in an intact oligosaccharide, or by an endoglycosidase leading to an oligosaccharide deprived of the *N*-acetylglycosamine linkage. No well-characterized enzyme systems are available today that are capable of general release of O-linked oligosaccharides.[826] Released fragments are usually subjected to further enzymatic cleavage by exo- or endoglycosidases of high specificity, targeting particular glycosidic linkage patterns in the oligosaccharide, whereafter the fragments are separated and identified.[827] Large amounts of structural information can be produced in a short time if arrays of enzymes are used. The most recent developments in this area dispose of the chromatographic separation step entirely and carry out the enzymatic reactions directly on a MALDI target.[828] Yet modern biomacromolecule chromatography is indispensable in glycobiology, because the purity of the enzymes used is obviously of paramount importance to the reliability of the data produced.

A combination of separation techniques into multidimensional separation schemes is required to elucidate the complicated structures of oligosaccharides in biological systems, and even three-dimensional separation maps with orthogonal selectivities have been described.[221] Several books on carbohydrate analysis have also been published during the 1990s.[829–831]

8.5 Validation of Separation Processes

From the preceding text, it is obvious that HPLC is becoming a viable alternative to many conventional techniques for preparative purification of proteins and other biotechnologically derived products, due to the high speed and separation potential. Whenever a chromatographic technique is adopted as part of a production scheme for a therapeutic formulation, stringent rules apply to the validation of the separation method. Aspects such as assessing the long-term consistency of retention, the possibility of cleaning and sterilizing separation columns in-place and the possible deterioration of phases due to such actions leading to release of leachable compounds are treated in a recent review by Jungbauer and Broschetti.[775]

9 TRENDS IN SEPARATION MEDIA FOR HIGH-PERFORMANCE LIQUID CHROMATOGRAPHY OF BIOMACROMOLECULES

During the 1990s, there has been a tremendous development in new separation media for biological macromolecules, in particular proteins.[96,832] Low diffusion coefficients are the Achilles' heel of large-molecule chromatography, leading to a steep decrease in efficiency resulting from the contribution to factor *C* (Equation 15) of the van Deemter–Knox equation (Equation 12). The activities aimed at improving the separation efficiency have therefore focused on the physical configurations of sorbents to enhance the mass transfer. Much less has been done in the area of chemistries of the separation media.

Efforts to improve mass transfer can be divided into three major areas:

- Decreasing the particle size to diminish the intraparticle diffusion length.
- Avoiding the intraparticle diffusion using active sites on nonporous supports (micropellicular materials).
- Facilitation of the intraparticle mass transfer by convection (Figure 70).[98]

9.1 Nonporous and Micropellicular Separation Media

Supports may be classified according to the spatial distribution of pores as nonporous, superficially porous, and totally porous.[96] Micrometer-sized nonporous silica particles were introduced in the 1980s as a means of alleviating the problem of mass transfer limitations that results from the slow intraparticle diffusion. Although the advantage of elimination of intraparticle diffusion could be demonstrated,[833,834] these nonporous particles have an extremely low surface area compared to porous media. As the separation proceeds mainly at the surface, both very low sample capacity and retention are typical for these packings. Based on a solid SiO_2 density of 2.2 g cm^{-3}, the surface area of a packed bed of 5 µm spherical particles is as low as 0.6 m^2 mL^{-1}, and even if the particle size is decreased to 1 µm, the surface area is increased to only 3 m^2 mL^{-1}. This is about two orders of magnitude lower surface area than the typical porous silicas useful for the separation of biological macromolecules. A comparison of porous and nonporous microparticulate RP silicas used in the separation of two closely related peptides also shows that the pellicular material is more sensitive to changes in the mobile phase due to the overall low coverage with interaction groups.[835] In a study of the effect of packing particle size on column efficiency in C_{18} RP separation of proteins on nonporous and porous silica, and on nonporous silica of different particle size,[836] all columns appeared to have essentially the same efficiencies, due to the binary sorption conditions during the steep gradients (Figures 71 and 72).

There are still substantial advantages inherent in the use of nonporous media. Solid particles are extremely hard and can tolerate very high differential pressure across the packed beds. The nonporous surface with a well-defined topography enables high accessibility of the interaction layer and the absence of pores ensures that separations are not affected by exclusion processes. In specific applications, the low retention can be used to an advantage, as it makes the use of mild eluents mandatory. In combination with a low column void volume, and the inherent high efficiency, columns packed with nonporous particles provide for very fast separations. This appears to be the principal advantage of nonporous microparticles.[832] Fast separation implies that denaturation can be kept at a minimum. Protein separations can be carried out at elevated temperatures

Figure 70 Overview of the routes taken to improve the separation efficiency for biological macromolecules by reducing the mass transfer resistance in the partitioning process. (Reproduced from A.E. Rodrigues, *J. Chromatogr. B*, **699**, 48 (1997) by permission of Elsevier Science B.V.)

Figure 71 Proteins separated on (a) 5-µm nonporous bonded C_{18}, and (b) 7-µm macroporous bonded C_{18} silica columns by conventional gradient elution at 2 mL min^{-1} and at ambient temperature. Eluents: (A) 0.1% TFA in water and (B) 0.1% TFA in 90% aqueous acetonitrile. Linear gradient from 10% to 100% B in 20 min. Peak identities: 1, insulin; 2, cytochrome *c*; 3, lysozyme; 4, BSA; 5, carbonic anhydrase; 6, insulin B chain; 7, α-lactalbumin. (Reproduced from N. Nimura et al., *J. Chromatogr.*, **585**, 209 (1991) by permission of Elsevier Science B.V.)

Figure 72 Fast protein separations on bonded C_{18} nonporous silica with particle diameter (a) 2 µm (b) 5 µm, and (c) 20 µm at 4 mL min^{-1} flow rate and 75 °C. Linear gradient from 22% to 100% eluent B (Figure 71) in 48 s. Peak identities: 1, insulin B chain; 2, insulin; 3, lysozyme; 4, α-lactalbumin; 5, carbonic anhydrase. Figures 71 and 72. (Reproduced from N. Nimura et al., *J. Chromatogr.*, **585**, 209 (1991) by permission of Elsevier Science B.V.)

to further enhance the separation. The decreased eluent viscosity promotes both diffusion and interaction kinetics and lowers the back-pressure. An example of a rapid separation under these conditions is shown in Figure 73. It should be noted that this separation is carried out under conditions that are denaturing the analytes even at normal temperature. Thus, the use of high temperature does not alter the situation. However, denaturing does not appear to be a major issue in analytical separation unless the purpose of the separation is elucidation of tertiary or higher protein structure, and can therefore be acceptable as long as the peaks are eluted singly in narrow bands at predictable retention times, and provided that the stationary phases are not irreversibly damaged by precipitated protein.

Obviously, separations on nonporous packings are limited to analytical and micropreparative scale because of the low loading capacity. Another consequence of the low capacity is the need for sensitive detection. Although this is partly compensated for by the high concentration of the analyte in narrow peaks, separations in columns packed with nonporous materials require more sensitive detection techniques.

The development of current micropellicular separation media represents a revival of technology of the early days of HPLC.[832] Many pellicular sorbents of that time were provided with thicker interaction layers compared to the current monolayer functionalized silicas. Today, the term micropellicular separation media is used to describe all smooth, nonporous particles that are monolayer functionalized,[838] or covered with polymer shrink-wraps,[135,142,143] superficially porous layers,[839] polymer tentacles,[163] and electrostatically attached layers of polymeric latex particles.[840] Pellicular layers can also have a polymeric core and an inorganic interaction layer.[15] Monolayers have little effect on increase of

Figure 73 Separation of (1) ribonuclease, (2) cytochrome *c*, (3) lysozyme and (4) β-lactoglobulin on a 30 × 4.6 mm i.d. column packed with 2-µm nonporous octadecyl silica using a 12-s gradient from 10% to 90% (v/v) acetonitrile (ACN) in water containing 0.1% TFA at a temperature of 120 °C and a flow rate of 5 mL min^{-1}. Column inlet pressure 240 bar. (Reproduced from H. Chen, Cs. Horváth, *Anal. Methods Instrum.*, **1**, 213–222 (1993) by permission of John Wiley & Sons.)

the loading capacity and merely serve the purpose of outfitting the surface area with a suitable interaction layer. This is similar to the processes used for functionalization of internal surfaces of porous beads. The same applies

to smooth and dense polymer shrink-wraps regardless of their thickness, as biomolecules typically interact only with the surface. However, the difference in loading capacity compared to a porous sorbent is lower than may be expected, because the interior surface of a porous material would be largely inaccessible to a slowly diffusing protein at the separation speeds used with nonporous microparticles,[100] evident also in Figure 71. A majority of the polymer coating techniques described earlier in the text have been used for coating smooth microparticles.

Most separation chemistries have been implemented on micropellicular media except, for obvious reasons, SEC. Unger showed that RP separation of proteins and peptides can be done with high efficiency on C_{18}, C_8, C_4, C_2, and phenyl-modified monodisperse 1.5-μm nonporous silica,[838] and that hydrophobic interaction chromatographic interaction layers can be established on these supports activated by diethylene glycol allyl methyl ether and acetamidopropyltriethoxysilane.[841] The recovery of proteins (pepsin, catalase, and horseradish peroxidase) in their native state on the RP materials showed the expected dependence on ligand chain length, solvent admixture, and contact time.[842] Coating with PBD was later shown to be a useful alternative for providing a hydrophobic coating on nonporous silica.[135]

Examples of affinity chromatographic separations are glycoproteins and Igs on columns with immobilized protein A, concanavalin A, or wheat-germ agglutinin,[100] and the separation of cytochrome *c*, lysozyme, and chymotrypsinogen A by rapid metal-interaction chromatography on IDA ligands charged with Co^{2+}, Fe^{3+} or Ni^{2+} ions.[843] Preparation of micropellicular silica phases with RP, anion exchange, and hydrophobic interaction surface layers and their use for rapid separation of proteins was demonstrated by Kalghatgi.[844] A micropellicular sorbent for HILIC based on aminofunctionalized nonporous silica was recently used by Lin and Lee for separation of a fructo–oligosaccharide mixture.[215]

Micropellicular sorbents prepared from 3-μm cross-linked polystyrene beads were used for separation of proteins in RP mode at different pH and temperature by Maa and Horváth.[845] Although some swelling was observed in organic solvents, typical RP eluents did not have any negative effect on the efficiency, which was found to be best at the extreme ends of the tested pH scale. Polystyrene beads were also functionalized with DEAE groups and used in anion-exchange mode for fast separation of DNA fragments with gradients of aqueous buffers as eluents.[846] Letourneur et al.[847] converted nonporous polystyrene into phosphate-type ion exchangers. The pellicular separation media most widely used are the ion exchange resins with agglomerated latex coating first described by Small et al.[840] for the separation of small ions by IEC. Modern tentacle-type sorbents with application areas directed towards separations of biomacromolecules[575] originated from this work.

A different type of nonporous medium, deswollen and cross-linked agarose beads, was described by Hjertén and Liao.[848,849] These particles are prepared by suspending macroporous agarose beads in a solvent mixture that contains dioxane and chloroform, followed by cross-linking of the shrunken beads with 1,4-butanediol diglycidyl ether. This treatment leads to particles with diameters as small as 3 μm, with sufficient mechanical stability to be packed and used for separation. However, the cross-linking renders the agarose more hydrophobic and makes it suitable for HIC.[848] Treatment with glycidol enhances the hydrophilicity of the surface. Functionalization to an anion exchanger and its use in IEC of a number of proteins was also demonstrated[849] (Figure 74). Yet another variety of nonporous support are 0.5-μm quartz fibers, which were silylated with mercaptopropyltrimethoxysilane and coupled with tresyl chloride-activated dextran by Wikström and Larsson to afford affinity supports. After derivatization with a NAD (nicotinamide adenine dinucleotide) ligand, this medium was used for rapid processing of enzymes from dilute solutions.[310]

Figure 74 Separation of proteins on a compressed, nonporous anion exchange column (62 × 6 mm i.d.; 15 μm) prepared by reacting with dimethylamine a macroporous agarose that had been rendered nonporous, cross-linked, and activated by 1,4-butanediol diglycidylether in solvent. Linear gradient over 2.5 min from (A) 10 mM TRIS-HCl, pH 8.5, to (B) 180 mM sodium acetate in (A), at a flow rate of 4 mL min^{-1}. Proteins: 1, myoglobin; 2, haemoglobin; 3, transferrin; 4, ovalbumin; 5, serum albumin; 6, phycoerythrin. (Reproduced from J.L. Liao, S. Hjertén, *J. Chromatogr.*, **457**, 180 (1988) by permission of Elsevier Science B.V.)

Two reviews have been published on the use of nonporous stationary phases in biomacromolecule separations. Lee[97] focuses on the preparation and functionalization of nonporous sorbents and the dynamics of protein separation and offers a comprehensive listing of commercially available nonporous sorbents; the topic of Huber[715] is separation of double-stranded DNA on micropellicular stationary phases by anion-exchange or ion pair chromatography. Chen and Horváth placed micropellicular sorbents in a wider perspective of HPLC development in their review of high-speed HPLC of peptides and proteins.[832]

9.2 Perfusion-type Particles with Large Open or Gel-filled Pores

As outlined in the introductory part of this article, the main obstacle against high efficiency separations, with a sample capacity sufficient for preparative applications on conventional porous sorbents, is the intraparticle mass transfer resistance, i.e. the pools of stagnant mobile phase that the solutes have to move across in order to interact with the internal pore surfaces. One way of enhancing the mass transport in porous media, through augmented diffusivity by convection, was described in the chemical engineering literature in the early 1980s.[850] After the concept was applied to protein separation media in the late 1980s,[851] the technique became known as perfusion chromatography. The underlying principle is quite straightforward. By ascertaining that the sorbent has a sufficiently large pore size, the differential pressure across the particle forces part of the eluent through the sorbent particle, in addition to the flow around it through the interstitial voids. This convective transparticle flow enhances the mass transfer through the macroporous space within the beads, so that the solutes are brought more quickly into contact with the interacting sites. A transparticle flow of only a few percent of the total flow is sufficient to increase the efficiency substantially. Characteristic of convective transport is that the factor C in the van Deemter–Knox equation levels off at a critical flow rate, and that the efficiency beyond that point becomes nearly independent of the eluent flow velocity. In other words, the column throughput per unit time increases almost linearly with eluent flow rate, without a band-broadening penalty. Another beneficial effect of the more efficient mass transport in the convective regime is that, unlike conventional porous sorbents, the useful dynamic capacity of the sorbent is preserved at high flow rates. The theory of convection-enhanced internal mass transport in particles has been worked out by Rodrigues et al.,[98,850,852–859] Liapis et al.,[860–871] and by Carta et al.[855,872–876] For example, the extended version of the van Deemter–Knox equation (the Rodrigues equation) adequately describes the mass transfer enhancement for biomacromolecules in perfusive sorbents (Figure 75).

Perfusive sorbents are typically used as relatively large particles (10–40 μm) in small to medium scale preparative separations. They can therefore be operated in the augmented transport regime at high linear flow rates without excessive back-pressure. The most valuable feature of perfusion chromatography is the speed of separation, which allows high throughput processing using relatively small columns operated in automated systems.

There are currently two different types of augmented diffusivity materials on the market, contrasting with respect to the medium occupying the pore system. The material first introduced[851] is manufactured from a megaporous styrene–divinylbenzene sorbent with a bimodal pore size distribution. These sorbents contain very wide pores with a diameter of 600–800 nm transecting clusters of spheroid microglobules containing 50–150 nm small diffusion pores that also account for the majority of the interaction surface area. Another material, introduced a few years later, is a soft-gel-in-a-rigid-shell aerogel–xerogel composite, comprising a rigid hyperporous polystyrene–silica composite that has the pore space filled with a lightly cross-linked soft hydrogel, which is also the carrier of the interactive groups.[877] The presence of a hydrogel inside the pore system increases the capacity[878] and lowers the eluent flow rate where the transition from the diffusive to the convective operation takes place, so that the efficiency is independent of flow rate in practically the entire operational range.[856]

Superporous agarose, prepared by Gustavsson and Larsson[879] using the double emulsifier technique, has also the attributes of a perfusion sorbent, although the size of both particles (300–500 μm) and the through-pores

Figure 75 Typical flow rate dependence of the height of a theoretical plate (H) for conventional porous and perfusion supports. (Reproduced from A.E. Rodrigues, *J. Chromatogr. B*, **699**, 50 (1997) by permission of Elsevier Science B.V.)

(25–75 μm) are considerably larger than those of the rigid synthetic porous polymers discussed above. For this reason it hardly qualifies as an HPLC sorbent. In fact, the intraparticle superpores are so large that the convective flow can be monitored by videomicroscopy of dyed microparticles moving through the pores.[880] The advantages of intraparticle flow within these beads have been demonstrated in ion-exchange,[879] hydrophobic interaction,[881] and affinity chromatography.[882] A similar material was also used for the preparation of continuous monolithic beds[883] (see below). The applications of superporous agarose are in large-scale purifications.

9.3 Media with Reduced Discontinuity – Membranes, Rolled Sheets, and Monoliths

Although the lowest theoretical interparticular volume of perfectly packed uniformly sized spherical beads is calculated to be about 27% of the total column volume, the void volumes of even the best packed columns are in practice substantially larger. Separation in a medium which is essentially a single piece and does not contain interparticular voids normally contributing to peak broadening has been treated theoretically[884] but experimental work remained scarce as a result of the lack of better alternatives to beads.

The problem of interparticular volume does not exist in systems in which a membrane is used as the separation medium. Both theoretical calculations and experimental results[283] clearly demonstrate that membrane systems can be operated in a dead-end, or filtration mode, at much higher flow rates than packed beds, because all the substrate solution flows through the support and the mass transfer is much faster as a result of this convective flow. Obviously, a reasonable compromise between the membranes with their fast mass transfer and beads with high capacity may result in separation media with enhanced properties.

The simplest available porous membrane is filter paper made of pure cellulose fibers. Numerous modification methods have been described for this material and applications of microcrystalline cellulose powders in chromatography of biopolymers are well known. These may be the most important reasons for the use of modified cellulose sheets (membranes) in various separation devices. As the binding capacity of a single sheet would be too small, commercial membrane cartridges contain several membranes stacked and placed in specifically designed cartridges. The pore size of these membranes is an important variable that effects the separation of proteins.[885] As a result of their large width and low height, membrane cartridges allow for high volumetric throughputs at low back-pressure. The residence time within the cartridge is generally short and thus the danger of denaturation of biopolymers during the separation process is largely reduced. Numerous analytical and preparative separations of proteins in various chromatographic modes have been performed in membrane cartridges with very good results.[78,886,887]

Theory predicts a dramatic increase in efficiency for adsorptive membrane devices compared to that of beds packed with particles, perhaps by a factor of 10.[887] However, the nonuniform flow and dead volumes typical of many current cartridges[888] do not fully utilize the intrinsic separation ability of the membranes, and therefore their design must be improved to compete successfully with packed columns. The problem of distorted flow and voids between the membranes in the stack does not exist in cartridges that accommodate only a single thicker disk of porous material. Additionally, Belenkii's theory of critical distance in adsorption chromatography leads to a conclusion that even a very short layer of a separation medium such as the disk can be sufficient for an efficient separation of large molecules.[889] These provisions led to the development of rigid disks for rapid chromatography of biopolymers in the late 1980s.[77]

Flat slabs and rods of porous material are easily prepared in a single step by free-radical polymerization within a closed mold. Disks are cut with a blade from the sheets or machined from the rod and placed into special cartridges. If needed, the porous material can be provided with desired functionalities by chemical modification. Typically, the molded material is wetted with the solution of a reagent and the modification is performed in a flask.[890] Josic et al. studied numerous applications of rigid macroporous disks[891,892] and found that a well-designed cartridge in combination with optimized disks dramatically improved the performance and allowed for a rapid chromatography of proteins. The separations of protein mixtures in different chromatographic modes, such as ion-exchange and hydrophobic interaction, were easily achieved in a few seconds[892] (Figure 76). Macroporous disks using this technology have been commercialized.

Disks of regenerated cellulose provided with ion-exchange functionalities and placed in disposable cartridges are also commercially available. These devices are characterized by very large through-pores that allow direct purification of dirty feedstocks such as homogenized yeast cells at high flow rates.[893]

Ladisch fabricated stationary phases prepared from rolled flat soft materials–woven textile fabric.[894] The cylindrical roll is inserted into a typical HPLC column blank. The number of chemistries is limited by the variety of fibers. Aramid columns behave as a hydrophobic interaction phase, whereas cotton fabrics transformed to an ion-exchange derivative can be used in IEC.[895] Rolled columns are very stable and have much better flow

Figure 76 Separation on a rigid macroporous disk applied to in-process analysis during α_1-antitrypsin (AAT) production. (A) A sample containing 5 mg mL^{-1} of AAT, with 5 mg mL^{-1} each of HSA and transferrin (Tf) as impurities. (B) Purified AAT (5 mg mL^{-1}). The separation element was a 25-mm diameter, 3-mm thick GMA-EDMA disk with DEAE functionality. Buffer A, 10 mM TRIS-HCl, pH 7.4; Buffer B, 1 M NaCl in buffer A. Gradient: 0–100% Buffer B in 30 s at 5 mL min^{-1}; back-pressure, 800 kPa; room temperature. Detection: UV, 280 nm. Peak identities: 1, Tf; 2, AAT; 3, HSA. (Reproduced from A. Strancar et al., *Anal. Chem.*, **68**, 3486 (1996) by permission of American Chemical Society.)

properties than columns packed with less than 1-mm short fibers.[896] As expected, the efficiency (plate height) does not change with flow velocity because the mass transfer is substantially enhanced by convection of the mobile phase through the stationary phase. Kennedy and Paterson used a similar approach and rolled a rod from a paper-like cellulose sheet.[897] After cyanogen bromide or CDI activation, Protein A and Protein G were immobilized onto the cellulose and the column was successfully used for the affinity separation of IgG.

Slightly cross-linked polyacrylamide beads have been known for a few decades as excellent packing for the low-pressure LC of biomacromolecules. The general perception is that their swelling and softness prevent them from use in tall chromatographic columns. However, a study of the resolving power of another soft gel material – agarose beads – revealed that compressed beds of these particles had better efficiency than the original columns.[105] Hjertén et al. transformed this experience into the preparation of highly cross-linked (30–60%) methylenebisacrylamide copolymers with functional monomers that were packed into columns and compressed to a fraction of their original volume before use in chromatographic separations.[127] Although plugs have a porosity of about 66%, this porosity mainly represents large pores, whereas the highly cross-linked and compressed nodules are nonporous for proteins.[898] Therefore, separations of large molecules are rather fast. This technology was later extended to the preparation of microcolumns. Materials for chromatographic separations in different modes are obtained either directly by copolymerization that involve different charged or hydrophobic monomers or using in situ modifications.[899] These compressed beds are now commercialized.[900,901] Both quaternary ammonium and sulfonic acid columns for IEC are claimed to have good stability and a high dynamic binding capacity that does not change with an increase in flow velocity. For example, the strong cation-exchange type binds 42 mg of bovine IgG per milliliter of column volume.

Another procedure in which rigid macroporous materials of any desired shape are prepared in their final size is in situ polymerization, developed in the early 1990s.[902] As can be implied, these separation media are not packed but molded within the confines of the tube of a chromatographic column. In this procedure, the column tube (sealed at one end) is filled with the polymerization mixture; then it is sealed at the other end and heated in a water bath. Once the polymerization is complete, the seals are removed and the column is provided with fittings, attached to the HPLC system, and washed. Obviously, an ideal monolith should contain both large pores to achieve a mobile phase flow through the column at a reasonable back-pressure (convection), and a connected network of shorter and smaller pores for diffusion. Indeed, an extensive study of the effects of individual variables of bulk polymerization on the porous properties of products, with particular attention paid to temperature (polymerization kinetics) and porogen composition (phase separation process), led to highly porous monolithic materials with a bimodal pore size distribution that is completely different from that found for macroporous beads prepared from identical polymerization mixtures. Typically, these monoliths contain not only small diffusive pores, but also a large number of flow-through pores with diameters in the range of 700 to 2000 nm.[903,904] This structure accelerates mass transfer of the sample within the porous material by convection, resulting in faster chromatographic runs without sacrificing the separation power of the monolithic column.

Poly(styrene–divinylbenzene) monoliths are well suited for the rapid separation of proteins in the RP mode with an efficiency on par with micropellicular materials, although at a substantially lower back-pressure[905] (Figure 77). An application showing the potential of this concept is the preparation of monolithic styrene–divinylbenzene in pulled electrospray needles, enabling separation and direct on-line determination of peptides in an MS system with low background noise.[906] Rigid reactive poly(glycidyl methacrylate–ethylene dimethacrylate) monoliths can be easily

Figure 77 Rapid RP separation of (1) ribonuclease, (2) cytochrome *c*, (3) BSA, (4) carbonic anhydrase, and (5) ovalbumin on a 50 × 4.6 mm i.d. monolithic poly(styrene–divinylbenzene) column at a flow rate of 10 mL min^{-1}. provided with special functionalities such as ion-exchange or hydrophobic groups by chemical modification. The experimental work done so far confirms the potential of these molded continuous supports. In addition to RP, HIC, IEC, and precipitation chromatography, these materials have also been used for CEC.[907]

Tanaka et al. reported the preparation of C_{18}-modified silica-based monolithic columns in the mid-1990s.[909] A single piece of porous material was obtained by hydrolytic polymerization of tetramethoxysilane in the presence of poly(ethylene oxide) and catalytic amounts of acetic acid in a plastic mold. The material was removed from the mold, treated subsequently with aqueous ammonia and nitric acid, washed with methanol, and dried. The final structural features of the porous silica were obtained after 2 h of heating to 600 °C. The material was finally machined to the column shape and placed in a cartridge. Although this process is more complex than the direct in situ polymerization used for the preparation of monolithic columns from porous organic polymers, the columns afforded efficiencies of up to 96 000 plates per meter for alkylbenzenes[909,910] and a remarkable 20 000 plates per meter for the separation of insulin at a high flow velocity of 5 mm s^{-1}.[911] This excellent performance appears to arise primarily from the specific morphology of these materials, which have an unusually high level of pore connectivity and possess a larger volume of mesopores (Figure 78).

Among the numerous advantages of monolithic columns are their ruggedness, the versatility of their chemistries, and their excellent efficiency in the separation of biological and synthetic molecules.

9.4 Temperature-responsive Chromatography

A significant recent trend in biological macromolecule separations is the use of interaction surfaces capable of undergoing rapidly and controlled morphological changes in response to changes in their environment, which in turn alters the interaction characteristics. The best studied of these phenomena are the intra- and intermolecular interactions of side-chains of linear synthetic polymers, which in some polymers carrying side-chains of suitable polarity and shape causes an abrupt temperature-dependent morphological transition known as a critical solution temperature transition. In response to increased temperature, these transitions can be both expansion–dissolution and contraction–precipitation. The distinct temperature-dependent phase phenomena observed for biopolymers, such as thermoreversibility of agarose and gelatin gels, and the melting of double-stranded DNA, are examples of critical solution temperature behavior. These kinds of reversible changes can be utilized in temperature-responsive chromatography.

The best known example of a temperature-responsive synthetic polymer is poly(*N*-isopropylacrylamide) (poly(NIPAAm)). Its thermal responsiveness has

Figure 78 Scanning electron micrograph of a porous monolithic silica rod. (Reproduced from H. Minakuchi et al., *Anal. Chem.*, **68**, 3499 (1996) by permission of the American Chemical Society.)

found use in immunoassay,[912] for modulating[913] and mimicking[914] enzyme activity, in electrochemical biosensor technology,[915] and in LC.[916–918] The characteristic that makes poly(NIPAAm) particularly interesting is the convenient location of the lower critical solution temperature at 32 °C, where drastic changes of the retention properties are observed.[128] The isopropyl group of NIPAAm has a hydrophobic character well suited for the HIC separation of proteins. This application was verified on a continuous-bed sorbent[919] and grafted layers on controlled pore glass[920] (Figure 79). The temperature-controlled retention allows the HIC separations to proceed with isocratic eluents, thus excluding the tedious equilibration with the starting mobile phase typical of gradient elutions.

Figure 79 Chromatograms of a polypeptide mixture on aminopropyl silica modified with a semitelechelic copolymer of *N*-isopropylacrylamide (96.8 mol %) and butyl methacrylate (3.2 mol %). Mobile phase: 0.5 M aqueous NaCl (pH 2.1), at (a) 5 °C and (b) 30 °C. Peak identities: (1) insulin chain A, (2) β-endorphin fragment 1–27, (3) insulin chain B. (Reproduced from H. Kanazawa et al., *Anal. Chem.*, **69**, 829 (1997) by permission of the American Chemical Society.)

9.5 Molecularly Imprinted Stationary Phases

Molecularly imprinted polymers (MIPs), conceptualized by Pauling as early as 1940,[921] have been the subject of systematic studies since the 1970s.[922] The driving force for pursuing MIPs as HPLC matrices is to prepare stationary phases with the ultimate selectivity – recognition of a single molecular species. This is accomplished by polymerization of a mixture of monomers around a template molecule, so that the three-dimensional shape of the template is imprinted in the polymer structure. The technique relies upon polar groups in the template being able to organize complementary functional groups on the monomers prior and during solidification of the system. This spatial organization is subsequently frozen by a dense cross-linking. The polymer block is thereafter ground and the template molecules extracted from the pores. The empty cavities have an ability to selectively sequester the template molecules and the spatially organized imprint can recognize chirality. The utility of MIP sorbents has mainly been demonstrated in the separation of racemic mixtures of small chiral compounds.[923] Although Pauling foresaw the preparation of ''synthetic antibodies'', it has not yet been possible to prepare MIPs with recognition capabilities for biomacromolecules approaching those found in biological systems. As recognition depends on sequential formation and breaking of several interaction points located in exactly shaped cavities, sorption and desorption reactions in sterically restricted locations become rate-limiting steps and the kinetics of current MIPs is therefore slow. Site inhomogeneity producing severe tailing is also often seen in demonstrated separations. Judging from the large numbers of reviews that have been published recently,[923–929] MIPs have not lost their appeal. However, the persistent challenges in their development are to obtain recognition for large molecules, and to accelerate the interaction kinetics. It appears that radically different designs of MIPs are needed to obtain recognition of biomacromolecules.[930]

9.6 Restricted Access Media

Restricted access media (RAM), also known as internal-surface reversed-phase (ISRP) sorbents, are porous beads where the functionalization of the perimeter is different from the internal pore system. The outward-facing surface of the particle is typically hydrophilic, whereas the inner surface is hydrophobic or carrying groups for specific interactions with solutes capable of entering the porous system.[931] They can be considered as mixed-mode sorbents with spatially segregated hydrophobicity controlled by a size-exclusion mechanism. Such materials are obviously not very useful for separation of biological macromolecules but their utility in separation

schemes for large molecules lies in the possibility of selectively interacting with small molecules that should be removed from macromolecules.[932] Internal-surface materials have also proven useful in the separation of cyclic peptides.[235]

10 CONCLUSIONS

It is virtually impossible to provide a complete and nuanced overview of an area as vast as the one covered by this article. Yet, it has hopefully been possible to communicate not only the basic problems associated with separation of biological macromolecules in LC, but also the possibilities created by recent developments in the area. An important distinction must be made between analytical separations and micro- or macropreparative separations by HPLC, a gap that has been narrowed through modern materials that merge soft separation techniques previously reserved for slow preparative separations into the HPLC format. The major tradeoffs are, as always, between separation efficiency, separation time, and capacity. A recurring issue has been ways of preventing denaturing, i.e. to preserve biological activity of the separated substances. Again, this issue is usually more important to biochemists than to analytical chemists, as long as the separation techniques are capable of resolving the solutes and presenting them to the detector in a form which allows identification and quantification. Although separation chemistries have been treated as if they were entirely separate from each other, biomacromolecules are themselves governing the interaction modes to a large extent. Their chromatographic behaviors are therefore usually a mix between different separation modes, where the combined properties of the solute, the support, the interaction groups, and the eluent are interacting in providing a retention according to a multitude of interaction mechanisms. By having provided abbreviated descriptions of each of these modes, the reader should be better prepared to make all the choices required in developing a method. However, in the end all biological macromolecules are unique, and any generalization is prone to fail when faced with the immense variability of biological systems.

Infrared (IR) spectroscopy has proved to be a powerful tool for studying biological molecules and the application of this technique to biological problems is continually expanding, particularly with the advent of Fourier transform infrared (FTIR) spectroscopy in recent decades. One of the great advantages of IR spectroscopy is that virtually any sample in virtually any state can be studied. Liquids, solutions, pastes, powders, films, fibers, gases and surfaces can all be examined with a judicious choice of sampling technique. Biological systems such as proteins, peptides, lipids, biomembranes, carbohydrates, pharmaceuticals, foods and both plant and animal tissues have all been successfully characterized using IR spectroscopy.[1–4]

IR spectrometers have been commercially available since the 1940s. At that time the instruments relied on prisms to act as dispersive elements, but by the mid 1950s, diffraction gratings had been introduced into dispersive machines. The most significant advances in IR spectroscopy, however, have come about with the introduction of Fourier transform spectrometers. This type of instrument employs an interferometer and exploits the well established mathematical process of Fourier transformation. FTIR spectroscopy has dramatically improved the quality of IR spectra and minimized the time required to obtain data. Also, with improvements to computers in recent years, IR spectroscopy has made great strides.

1 INTRODUCTION

In recent years FTIR spectroscopy has found increasing favor in laboratories.[2] This more recent method is based on the old idea of the interference of radiation between two beams to yield an interferogram. An interferogram is a signal produced as a function of the change of pathlength between the two beams. The two domains of distance and frequency are interconvertible by the mathematical method of Fourier transformation. Although the basic optical component of FTIR instruments, the Michelson interferometer, has been known for almost a century, it was not until advances in computing that the technique could be successfully applied. The basic components of a FTIR spectrometer are shown schematically in Figure 1. The radiation emerging from the source is passed through an interferometer to the sample before reaching a detector. Upon amplification of the signal, in which high frequency contributions have been eliminated by a filter, the data are converted to a digital form by an analog-to-digital converter and transferred to the computer for Fourier transformation.

The most common interferometer used is a Michelson interferometer, and consists of two perpendicularly plane mirrors, one of which can travel in a direction perpendicular to the plane (Figure 2). A semi-reflecting film, the beam splitter, bisects the planes of these two mirrors. If a collimated beam of monochromatic radiation of wavelength λ cm is passed into an ideal beam splitter, 50% of the incident radiation will be reflected to one of the mirrors and 50% will be transmitted to the other mirror. The two beams are reflected from these mirrors, returning to the beam splitter where they recombine and interfere. Fifty percent of the beam reflected from the fixed mirror is transmitted through the beam splitter and 50% is reflected back in the direction of the source. The beam which emerges from the interferometer at 90° to the input beam is called the transmitted beam and this is the beam detected in FTIR spectrometry.

Figure 1 The components of a FTIR spectrometer.

Figure 2 A Michelson interferometer.

Figure 3 Interferograms for polychromatic radiation.

The moving mirror produces an optical path difference between the two arms of the interferometer. For path differences of $(n + 1/2)\lambda$, the two beams interfere destructively in the case of the transmitted beam and constructively in the case of the reflected beam. The resultant interference pattern is shown in Figure 3 for a source of polychromatic radiation. The former is a simple cosine function but the latter is of a more complicated form because it contains all the spectral information of the radiation falling on the detector. The essential experiment to obtain a FTIR spectrum is to produce an interferogram with and without a sample in the beam and transforming the interferograms into spectra of (a) the source with sample absorptions and (b) the source without sample absorptions. The ratio of the former and the latter corresponds to a double beam dispersive spectrum.

2 SAMPLING METHODS

IR spectroscopy is a versatile experimental technique and it is relatively easy to obtain spectra from biological samples in solution or the solid state.[1] In this section we shall study how samples can be introduced into the instrument, the equipment required to obtain spectra and the pretreatment of samples will be discussed.

2.1 Transmission Methods

Transmission spectroscopy is the oldest and most basic IR method. The method is based upon the absorption of IR radiation at specific wavelengths as it passes through a sample. Liquid or solid forms can be analyzed using this technique.

There are several different types of transmission solution cells available. Fixed pathlength sealed cells are useful for volatile liquids, but cannot be taken apart for cleaning. Semi-permanent cells are demountable so that the windows can be cleaned. A semi-permanent cell is illustrated in Figure 4. The spacer is usually made of polytetrafluoroethylene (PTFE, Teflon®) and is available in a variety of thicknesses, allowing one cell to be used for various pathlengths. Variable pathlength cells incorporate a mechanism for continuously adjusting the pathlength and a vernier scale allows accurate adjustment. All these cell types are filled using a syringe and the syringe ports are sealed with PTFE plugs before sampling. An important consideration in the choice of IR cells is the type of window material. The material

Figure 4 A semi-permanent cell.

Table 1 Summary of some optical materials used in transmission IR spectroscopy

Window material	Useful range (cm^{-1})	Refractive index	Properties
NaCl	40 000–600	1.5	Soluble in water; slightly soluble in alcohol; low cost; fair resistance to mechanical and thermal shock; easily polished
KBr	43 500–400	1.5	Soluble in water and alcohol; slightly soluble in ether; hygroscopic; good resistance to mechanical and thermal shock
CaF_2	77 000–900	1.4	Insoluble in water; resists most acids and bases; does not fog; useful for high pressure work
BaF_2	66 666–800	1.5	Insoluble in water; soluble in acids and NH_4Cl; does not fog; sensitive to thermal and mechanical shock
KCl	33 000–400	1.5	Similar properties to NaCl but less soluble; hygroscopic
CsBr	42 000–250	1.7	Soluble in water and acids; hygroscopic
CsI	42 000–200	1.7	Soluble in water and alcohol; hygroscopic

must be transparent to the incident IR radiation and normally alkali halides are used in transmission methods. The cheapest material is sodium chloride (NaCl), but other commonly used materials are listed in Table 1. Liquid films provide a quick method of examining liquid samples. A drop of liquid may be sandwiched between two IR plates which are then mounted in a cell-holder. The type of spectrum expected from a liquid film is illustrated in Figure 5, which shows the spectrum of chloroform, a solvent commonly used for biological samples.

Before producing an IR sample in solution, a suitable solvent must be chosen. In choosing a solvent there is a number of factors to be considered. A solvent must obviously be able to dissolve the compound. It should also be as nonpolar as possible to minimize solute–solvent interactions. In addition, the solvent should not strongly absorb IR radiation. If quantitative analysis is required it is necessary to use a cell of known pathlength. A guide to pathlength selection for different solution concentrations is shown in Table 2.

Water is a commonly used solvent for biological samples and NaCl cannot be used as a IR window material as it is very soluble in water. Small pathlengths (~0.010 mm) are available and help reduce the intensity of the very strong IR modes produced in the water spectrum. The small pathlength also produces a small sample cavity, allowing samples in milligram quantities to be examined. Certain difficulties arise when using water as a solvent in IR spectroscopy. The IR modes of water are very intense and may overlap with the sample modes of interest. This problem may be overcome by substituting water with deuterium oxide (D_2O). The IR modes of D_2O occur at different frequencies to those observed for water because of the mass dependence of the vibrational frequency. Table 3 lists the characteristic bands observed for both H_2O and D_2O.

There are three general methods for examining solid samples in transmission IR spectroscopy: alkali halide discs, mulls and films. A choice of method depends very much on the nature of the sample to be examined. The use of alkali halide discs involves mixing a solid sample (a few mg) with a dry alkali halide powder (100–200 mg). The mixture is usually ground with an agate mortar and pestle and subjected to a pressure of about 10 ton in^{-2} (1.575×10^5 kg m^{-2}) in an evacuated die. This sinters the mixture and produces a clear transparent disc. The most commonly used alkali halide is potassium bromide (KBr), which is completely transparent in the mid-IR region.

Certain factors need to be considered when preparing alkali halide discs. The ratio of the sample to alkali halide is important. Surprisingly little sample is needed and approximately 2 to 3 mg of sample with about 200 mg of halide should be used. The disc must not be too thick or too thin. Thin discs are fragile and difficult to handle, while thick discs transmit too little radiation. A disc of about 1 cm diameter made from about 200 mg of material usually results in a good thickness of about 1 mm. If the crystal size of the sample is too large excessive scattering of radiation results, particularly so at high wavenumbers. The crystal size must be reduced, normally by grinding the solid using a mortar and pestle. If the alkali halide is not perfectly dry this results in the appearance of bands due to water. Contributions due to water are difficult to avoid, and the alkali halide should be kept desiccated and warm prior to use.

The preparation of mulls for solid samples involves grinding the sample then suspending it (about 50 mg) in 1–2 drops of a mulling agent. This is followed by further grinding until a smooth paste is obtained. Ideally a mulling agent should be IR transparent between 4000 and 600 cm^{-1}, but no such agent exists. The most commonly used mulling agent is liquid paraffin (Nujol®), and its

Figure 5 The IR spectrum of chloroform.

Table 2 Pathlength selection for solution cells

Concentration (%)	Pathlength (mm)
>10	0.05
1–10	0.1
0.1–1	0.2
<0.1	>0.5

Table 3 The major IR bands of water and deuterium oxide

Frequency (cm^{-1})	Assignment
3920	O–H stretching
3490	O–H stretching
3280	O–H stretching
1645	H–O–H bending
2900	O–D stretching
2540	O–D stretching
2450	O–D stretching
1215	D–O–D bending

spectrum is shown in Figure 6. Although the mull method is quick and easy, there are some points to consider. The ratio of the sample to mulling agent must be appropriate as if there is too little sample and there will be no sign of the sample in the spectrum. Too much sample and a thick paste will be produced and no radiation will be transmitted. A rough guide to mull preparation is to use a micro spatula tip of sample to 2–3 drops of mulling agent. If the crystal size of the sample is too large this leads to scattering of radiation, which gets worse at the high frequency end of the spectrum. If the mull is not spread over the whole plate area, the beam of radiation passes part through the mull and part through only the plates, producing a distorted spectrum. Care should also be taken not to use too much or too little mull between the IR plates. Too little leads to a very weak spectrum showing only the strongest absorption bands. Too much mull leads to poor transmission of radiation so that the baseline may be at 50% or less. It is sometimes possible to reduce the energy of a reference beam to a similar extent by use of an attenuator. Beam attenuators work somewhat like a venetian blind, illustrated by Figure 7.

Films can be produced by either solvent casting or by melt casting. In solvent casting the sample is dissolved in an appropriate solvent (the concentration depends on the required film thickness). A solvent must be chosen which not only dissolves the sample, but will also produce a uniform film. The solution is poured onto a leveled glass plate (such as a microscope slide) or a metal plate and spread to uniform thickness. The solvent may then be evaporated in an oven and, once dry, the film can be stripped from the plate. However, care must be taken

Figure 6 The IR spectrum of liquid paraffin (Nujol®).

Figure 7 A beam attenuator.

as heating biological samples may cause degradation. Alternatively, it is possible to cast a film straight onto the IR window to be used. Solid samples which melt at relatively low temperatures without decomposition can be prepared by melt casting. A film is prepared by hot pressing the sample in a hydraulic press between heated metal plates.

2.2 Reflectance Methods

Reflectance techniques can be used for samples which are difficult to analyze by the normal transmittance methods. Reflectance methods can be divided into two categories. Internal reflectance measurements can be made using an attenuated total reflectance (ATR) cell in contact with the sample. There are also external reflectance measurements which involve an IR beam reflected directly from the sample surface.

Figure 8 An ATR cell.

ATR spectroscopy utilizes the phenomenon of total internal reflection (Figure 8).[5] A beam of radiation entering a crystal will undergo total internal reflection when the angle of incidence at the interface between the sample and crystal is greater than the critical angle. The critical angle is a function of the refractive indices of the two surfaces. The beam penetrates a fraction of a wavelength beyond the reflecting surface and when a material which selectively absorbs radiation is in close contact with the reflecting surface, the beam loses energy at the wavelength where the material absorbs. The resultant attenuated radiation is measured and plotted as a function of wavelength by the spectrometer and gives rise to the absorption spectral characteristics of the sample. The depth of penetration in ATR is a function of wavelength (λ), the refractive index of the crystal and the angle of incident radiation (θ). The depth of penetration, d_p, for a nonabsorbing medium is given by Equation (1):

$$d_p = \frac{\lambda/n_1}{\{2\pi[\sin\theta - (n_1/n_2)^2]^{1/2}\}} \quad (1)$$

where n_1 is the refractive index of the sample and n_2 is the refractive index of the ATR crystal. The crystals used in ATR cells are made from materials which have low solubility in water and are of very high refractive index. Such materials include zinc selenide (ZnSe), germanium

Table 4 Materials used as ATR crystals and their properties

Window material	Useful range (cm^{-1})	Refractive index	Properties
KRS-5 (thallium/ iodide)	17 000–250	2.4	Soluble in bases; slightly soluble in water; insoluble in acids; soft; highly toxic (handle with gloves)
ZnSe	20 000–500	2.4	Insoluble in water, organic solvents, dilute acids and bases
Ge	5000–550	4.0	Insoluble in water; very brittle

(Ge) and thallium/iodide (KRS-5). The properties of these commonly used materials for ATR crystals are summarized in Table 4. Different designs of ATR cells allow both liquid and solid samples to be examined. It is also possible to set-up a flow-through ATR cell by including an inlet and outlet into the apparatus. This allows for continuous flow of solutions through the cell and permits spectral changes with time to be monitored. Multiple internal reflectance (MIR) and ATR are similar techniques, but MIR produces more intense spectra from multiple reflections. While a prism is usually used in ATR work, MIR uses specially shaped crystals which cause many internal reflections, typically 25 or more (Figure 9).

In external reflectance incident radiation is focused onto the sample and two forms of reflectance can occur: specular and diffuse. External reflectance measures the radiation reflected from a surface. The material

Figure 9 A MIR cell.

Figure 10 Specular reflectance.

must, therefore, be reflective or be attached to a reflective backing. A particularly useful application for this technique is the study of surfaces.

Specular reflectance occurs when the reflected angle of incident radiation equals the angle of incidence (Figure 10). The amount of light reflected depends on the angle of incidence, the refractive index, surface roughness and absorption properties of the sample. For most materials the reflected energy is only 5–10%, but in regions of strong absorptions the reflected intensity is greater. The resultant data appears different from normal transmission spectra, as derivative-like bands result from the superposition of the normal extinction coefficient spectrum with the refractive index dispersion (based upon Fresnel's relations from physics). However, the reflectance spectrum can be corrected using a Kramers–Kronig transformation (or K–K transformation). The corrected spectrum appears like the familiar transmission spectrum.

Increased pathlengths through thin coatings can be achieved using grazing angles of incidence (up to 85°). Grazing angle sampling accessories allow measurements to be made on samples over a wide range of angles of incidence. Solid samples, particularly coatings on reflective surfaces, are simply placed on a flat surface. The technique is also commonly used for liquid samples which can be poured into a PTFE trough. Oriented films on the liquid surface can be investigated using this material. The grazing angle approach can be used to study surfactants, proteins, steroids and phospholipids in biological membranes.

In external reflectance, the energy which penetrates one or more particles is reflected in all directions. This component is called diffuse reflectance. In the diffuse reflectance infrared technique, commonly called (DRIFT), a powdered sample is mixed with KBr powder. The DRIFT cell reflects radiation to the powder and collects the energy reflected back over a large angle.

Figure 11 Diffuse reflectance.

Figure 12 The diffuse reflectance spectrum of aspirin.

Diffusely scattered light can be collected directly from a sample or, alternatively, using an abrasive sampling pad. DRIFT is particularly useful for sampling powders or fibers. Figure 11 shows diffuse reflectance from the surface of a sample. Kubelka and Munk[6] developed a theory describing the diffuse reflectance process for powdered samples which relates the sample concentration to the scattered radiation intensity. The Kubelka–Munk equation is Equation (2):

$$\frac{(1-R_\infty)^2}{2R_\infty} = \frac{c}{k} \tag{2}$$

where R_∞ is the absolute reflectance of the layer, c is the concentration and k is the molar absorption coefficient. Figure 12 shows the diffuse reflectance spectrum of aspirin. An alternative relationship between the concentration and the reflected intensity is now widely used in near-IR diffuse reflectance spectroscopy. The relationship is analogous to the Beer–Lambert law (Equation 3):

$$\log\left(\frac{1}{R}\right. = k'c \tag{3}$$

where k' is a constant.

2.3 Microsampling Methods

It is possible to combine an IR spectrometer with a microscope facility in order to study very small quantities.[7] In recent years there have been considerable advances in FTIR microscopy with samples as small as 25 μm being characterized. In FTIR microscopy, the microscope sits above the FTIR sampling compartment. IR radiation from the spectrometer is focused onto a sample placed on a standard microscope $x-y$ stage. After passing through the sample, the IR beam is collected by a Cassegrain objective which produces an image of the sample within the barrel of the microscope. A variable aperture is placed in this image plane. The radiation is then focused on a small area mercury cadmium telluride detector by another Cassegrain condenser. The microscope also contains glass objectives to allow visual inspection of the sample. In addition, by switching mirrors in the optical train, the microscope can be converted from transmission mode to reflectance mode.

If a microscope facility is not available, there are other special sampling accessories available to allow examination of microgram or microlitre amounts. This is accomplished using a beam condenser so that as much as possible of the beam passes through the sample. Microcells are available with volumes of around 4 μL and pathlengths up to 1 mm.

There are a number of microsampling cells available. A diamond anvil cell (DAC) uses two diamonds to compress a sample to a thickness suitable for measurement and increase the surface area. This technique can be used at normal atmospheric pressures, but it may also be applied to study samples under high pressures and improve the quality of the spectrum of trace samples.

A MIR cell can also be used as this technique can produce strong spectra. The ability to obtain spectra from trace amounts of materials is illustrated in Figure 13,

Figure 13 The IR spectra of phenacetin deposited on a micro MIR crystal: (i) 1 μg sample, spectrum recorded in 30 s; (ii) 50 ng sample, spectrum recorded in 2 min (resolution of 4 cm^{-1} in both cases). (Reproduced with permission from a Perkin-Elmer sales leaflet.)

which shows the IR spectra of the pain relieving drug phenacetin deposited onto a micro MIR crystal.

2.4 Gas Chromatography/Infrared

IR spectroscopy has been combined with various other analytical techniques. Gas chromatography/infrared spectroscopy (GC/IR) allows the identification of the components eluting from gas chromatography (GC).[8] GC/IR has certain advantages over, say, gas chromatography/mass spectrometry (GC/MS). While GC/MS is able to distinguish easily between compounds of different mass, it is unable to differentiate structural isomers of the same molecular mass. By comparison, GC/IR can easily distinguish isomers.

Figure 14 shows a schematic diagram of a typical for combining system GC with FTIR. The apparatus consists of a FTIR spectrometer, a gas chromatograph, light pipe, detector and a computer for analysis. The light pipe interfaces the GC with the spectrometer. The pipe is usually made of quartz and should be approximately one-half the width of the GC peaks for the best compromise between chromatographic resolution and IR sensitivity. For capillary column GC, the light pipe usually has a 1 mm inner diameter and for packed columns a light pipe of inner diameter 2–3 mm is used.

The nature of this technique requires that interferograms are collected in short time intervals. Gram–Schmidt chromatograms are created from the interferogram intensities and reflect the IR absorption. The Gram–Schmidt traces are a plot of IR absorbance versus time. The absorbance spectra of the eluted species are calculated by performing a Fourier transformation on the interferogram.

Figure 14 A combined GC and FTIR system.

IR spectroscopy has been combined with other established analytical techniques. For instance, with thermogravimetric analysis (TGA) which is a technique which involves measuring the change of mass of a sample when it is heated. While TGA can provide quantitative information about a decomposition process, it is unable to identify the decomposition products. However, TGA and IR have been combined to provide a complete qualitative and quantitative characterization of thermal decomposition processes.

2.5 Temperature Cells

Variable temperature cells can be obtained which are controlled to 0.1 °C in the range −180 to 250 °C. An electrical heating system is used for temperatures above ambient, and liquid nitrogen with a heater for low temperatures. These cells can be used to study phase transitions and the kinetics of reactions. As well as transmission temperature cells, variable temperature ATR cells and cells for microsampling are available.

3 SPECTRUM INTERPRETATION

Spectrum interpretation is simplified by the fact that the bands which appear can be assigned to particular parts of the molecule, producing what are known as group frequencies. The mid-IR region is normally treated as four regions, depending upon the type of group frequency. However, of certain factors which complicate IR spectra. Phenomena such as overtone and combination bands, Fermi resonance and hydrogen bonding can introduce additional, and sometimes misleading, information into the spectrum. It is important to be aware of these factors before tackling the interpretation of a given spectrum.

3.1 Group Frequencies

The mid-IR spectrum can be divided into four regions and the nature of a group frequency may generally be determined by the region in which it is located. These regions are defined as follows:

1. X−H stretching region (4000–2500 cm^{-1})
2. triple bond region (2500–2000 cm^{-1})
3. double bond region (2000–1500 cm^{-1})
4. fingerprint region (1500–600 cm^{-1}).

All the fundamental vibrations in the region 4000–2500 cm^{-1} may be attributed to X−H stretching. O−H stretching produces a broad band which occurs in the

range 3700–3600 cm^{-1}. By comparison, N–H stretching is usually observed between 3400 and 3300 cm^{-1}. This absorption is generally much sharper than O–H stretching and may therefore be differentiated. Compounds containing the NH_2 group usually show a doublet structure, while secondary amines show one sharp band. C–H stretching bands from aliphatic compounds occur in the range 3000–2850 cm^{-1}. They are moderately broad and show medium intensity. It is also possible to resolve asymmetrical and symmetrical C–H stretching absorptions of a CH_3 group which usually occur at about 2965 and 2880 cm^{-1}, respectively, while the corresponding absorptions for a CH_2 group occur at 2930 and 2860 cm^{-1}. If the C–H bond is adjacent to a double bond or aromatic ring, the C–H stretching frequency increases and absorbs between 3100 and 3000 cm^{-1}. This is useful in distinguishing purely aliphatic compounds, but must be used with care as for many compounds containing a small number of aromatic hydrogens and many aliphatic C–H bonds the peaks above 3000 cm^{-1} may only appear as a shoulder on the stronger aliphatic absorption and may be obscured. However, evidence for the presence of an aromatic ring may be obtained by examination of other regions of the spectrum. Deuterated compounds would be expected to show C–D stretching at a factor of 0.73 less due to the change in atomic mass. That is, at about 2130 cm^{-1}.

Triple bond stretching absorptions fall in the 2500–2000 cm^{-1} region because of the high force constants of the bonds. C≡C bonds absorb between 2300 and 2050 cm^{-1}, while the nitrile group (C≡N) occurs between 2300 and 2200 cm^{-1}. These groups may be distinguished since C≡C stretching is normally very weak, while C≡N stretching is of medium intensity. These are the most common absorptions in this region, but you may come across some X–H stretching absorptions, where X is a more massive atom like phosphorus or silicon. These absorptions usually occur near 2400 and 2200 cm^{-1}, respectively.

The principal bands in the 2000–1500 cm^{-1} region are due to C=C and C=O stretching. Carbonyl stretching is one of the easiest absorptions to recognize in an IR spectrum. It is usually the most intense band in the spectrum, and depending on the type of C=O bond, occurs in the region 1830–1650 cm^{-1}. Note also that metal carbonyls may absorb above 2000 cm^{-1}. C=C stretching is much weaker and occurs at around 1650 cm^{-1}. This band is often absent for symmetry or dipole moment reasons. C=N stretching also occurs in this region and is usually stronger. The N–H bending vibration in amines occurs between 1630 and 1500 cm^{-1} and is usually strong. Before assigning a band always check the N–H stretching region above 3000 cm^{-1} to avoid possible confusion.

At frequencies of values greater than 1500 cm^{-1} it is generally possible to assign each absorption band in an IR spectrum. This is not so for most absorptions observed below 1500 cm^{-1}. This region is referred to as the fingerprint region, since quite similar molecules give different absorption patterns at these frequencies.

It has been assumed so far that each band in an IR spectrum can be assigned to a particular deformation of the molecule, the movement of a group of atoms or the bending or stretching of a particular bond. This is possible for many bands, particularly stretching vibrations of multiple bonds which are well behaved. However, many vibrations are not so well behaved and may vary by hundreds of wavenumbers even for similar molecules. This applies to most bending and skeletal vibrations, which absorb in the 1500–650 cm^{-1} region, for which small steric or electronic effects in the molecule lead to large shifts. A spectrum of a molecule may have a hundred or more absorption bands present, but there is no need to assign the vast majority. The spectrum can be regarded as a 'fingerprint' of the molecule. Most single bonds absorb at similar frequencies and hence the vibrations couple. The observed pattern will depend on the carbon skeleton, and the resulting bands will originate from the oscillation of large parts of the skeleton, or the skeleton and the attached functional groups. C–C stretching frequencies may also couple with C–H bending vibrations. The C–O stretching frequency is one of the bands that can be useful for identification purposes. If no intense band appears in the fingerprint region, you can usually be sure that no C–O bonds are present. The frequency is rather variable, occurring anywhere between 1400 and 1000 cm^{-1}. Aromatic rings give rise to two bands at 1600 and 1500 cm^{-1}. They are usually sharp, but are of variable intensity and occasionally the band at 1600 cm^{-1} splits into a doublet. Aromatic rings and alkenes give rise to other bands which are perhaps the most useful in this region. They are out-of-plane C–H bending vibrations which occur between 1000 and 700 cm^{-1}.

The information provided by group frequencies can be summarized in what are known as a correlation tables. Figure 15 shows a correlation table for organic molecules. The lines in the correlation table represent the regions of the spectrum where bands appear for the relevent class of molecule.

3.2 Complicating Factors

Although it is a useful assumption to be make, it is not true that all bands in a spectrum can simply be associated with a particular bond or part of a molecule. Certain complicating factors need to be taken into account. One such factor is the presence of overtone and combination bands. Overtone bands in an IR spectrum are multiples of the fundamental absorption frequency. The energy levels for overtones of IR modes are illustrated in Figure 16. The

Figure 15 A correlation table for organic molecules.

energy required for the first overtone is twice the fundamental, assuming evenly spaced energy levels. Since the energy is proportional to the frequency absorbed and this is proportional to the wavenumber, the first overtone will appear in the spectrum at twice the wavenumber of the fundamental. Combination bands arise when two fundamental bands absorbing at $\bar{\nu}_1$ and $\bar{\nu}_2$ absorb energy simultaneously. The resulting band will appear at $(\bar{\nu}_1 + \bar{\nu}_2)$ wavenumbers. The absorptions observed in the near-IR region (13 000–4000 cm^{-1}) are overtones or combinations of the fundamental stretching bands that occur in the region 3000–1700 cm^{-1}. The bands involved are usually due to C–H, N–H, O–H, P–H or S–H stretching. The resulting bands in the near-IR are usually weak in intensity and the intensity generally decreases by a factor of 10 from one overtone to the next. The bands in the near-IR are often overlapped, making them less useful than the mid-IR region for qualitative analysis. However, there are important differences between the near-IR positions between functional groups and these differences can often be exploited for quantitative analysis. There are some classes of biological materials which can be successfully analyzed using near-IR spectroscopy, such as foods.

The Fermi resonance effect usually leads to two bands appearing close together when only one is expected.

Figure 16 Energy levels for fundamental and overtone IR bands.

When an overtone or a combination band has the same frequency as or a similar frequency to a fundamental, two bands appear split either side of the expected value and are of about equal intensity. The effect is greatest when the frequencies match, but it is also present when there is a mismatch of a few tens of wavenumbers. The two bands are referred to as a Fermi doublet.

The presence of hydrogen bonding is of great importance in biological molecules. For instance, the biological activity of DNA relies on this type of bonding. Hydrogen bonding can be defined as the attraction which occurs between a highly electronegative atom carrying a nonbonded electron pair (such as fluorine, oxygen or nitrogen) and a hydrogen atom, itself bonded to a small highly electronegative atom. An example of this type of bonding is illustrated by the interactions between

Figure 17 Hydrogen bonding of water molecules.

Figure 18 Intramolecular hydrogen bonding in a protein.

water molecules in Figure 17. This is an example of intermolecular hydrogen bonding. It is also possible for a hydrogen bond to form between appropriate groups within the one molecule. This is known as intramolecular hydrogen bonding and is illustrated by the protein structure shown in Figure 18. The segments shown belong to the same protein molecule.

Many solvents are capable of forming hydrogen bonds to solutes. To form a hydrogen bond a proton donor group and an electron donor group are needed. Three classes of solvent exist which may lead to trouble when used for hydrogen bonding studies is solution: compounds which contain hydrogen donor groups (e.g. halogenated compounds which contain a sufficient number of halogens to activate the hydrogens present, such as chloroform); compounds which contain nonbonded electron pairs (e.g. ethers, aldehydes, tertiary amines); compounds which contain both types of group (e.g. water and alcohols). There are only a few solvents which do not have the above characteristics, such as carbon tetrachloride (CCl_4) and carbon disulfide (CS_2). These still contain lone electron pairs but being on S and Cl are less available, and any interaction will therefore be extremely weak.

Figure 19 The effect of hydrogen bonding on a O–H stretching vibration.

Hydrogen bonding is a very important effect in IR spectroscopy. In IR spectroscopy the frequencies of vibration of bonds depend on the masses of the atoms in the bond and the bond stiffness. Hydrogen bonding influences the bond stiffness and so alters the frequency of vibration. For example, for a hydrogen bond in an alcohol, the O–H stretching vibration in a hydrogen bonded dimer is observed in the range 3500–2500 cm^{-1}, rather than the usual range 3700–3600 cm^{-1} (Figure 19). Apart from solvent effects, concentration and temperature also affect the degree of hydrogen bonding in a compound. The lower the concentration, the less chance there is of two molecules colliding. It follows that the degree of hydrogen bonding decreases with decreasing concentration. Increasing temperature means that each molecule will have more energy on average and hence weak associative forces, such as hydrogen bonds, are likely to be broken. This should lead to a lesser degree of hydrogen bonding, and thus changes in frequency to greater values would be observed for groups forming the hydrogen bond.

Another issue to be considered is coupling. Vibrations in the skeleton of molecules become coupled. In other words, they are not restricted to one or two bonds, but may involve a large part of the carbon backbone and oxygen or nitrogen atoms if present. The energy levels mix, resulting in the same number of vibrational modes, but at different frequencies, and bands can no longer be assigned to one bond. This is very common and occurs when adjacent bonds have closely similar frequencies. Coupling commonly occurs between C–C stretching, C–O stretching, C–N stretching, C–H rocking and C–H wagging motions. A further requirement is that to be strongly coupled the motions must be in the same part of the molecule. There are three factors which determine whether coupling will take place: the groups must be adjacent; the frequencies must be similar; and the vibrations must be in the same part of the molecule. It turns out that all vibrations which absorb in the region 1500–650 cm^{-1} will couple to an extent that critically depends on the shape of the molecule. Large groups, the presence of double and triple bonds and electronic effects will influence coupling. Hence it is difficult to predict the extent of this coupling and this leads to great difficulties in the assignment of bands in this region of the spectrum. This phenomenon accounts for the wide range of frequencies over which C–C, C–O and C–N stretching vibrations absorb. The most important consequence of coupling is that small changes in structure leads to major changes in the IR spectrum in the 1500–650 cm^{-1} region. It is very unlikely, therefore, that two different molecules will have exactly the same pattern of bands in this region.

3.3 Identification of Unknown Materials

There are a few general rules that can be stated to help in the use of an IR spectrum for the determination of a structure. However, the most effective way to learn is through practice. The following is a suggested strategy for spectrum interpretation:

1. Look first at the high-frequency end of the spectrum ($>1500\,cm^{-1}$) and concentrate initially on the major bands.
2. For each band, short list the possibilities using a correlation chart.
3. Use the lower frequency end of the spectrum for the confirmation or elaboration of possible structural elements.
4. Do not expect to be able to assign every band in the spectrum.
5. Cross-check wherever possible. For example, and aldehyde should absorb near $1730\,cm^{-1}$ and in the region $2900-2700\,cm^{-1}$.
6. Exploit negative evidence as well as positive evidence. For example, if there is no band in the $1850-1600\,cm^{-1}$ region, it is most unlikely that a carbonyl group is present.
7. Band intensities should be treated with some caution. Under some circumstances they may vary considerably for the same functional group.
8. Take care when using small frequency changes. These can be influenced by whether the spectrum was run as a solid or liquid or in solution. Some bands are very solvent sensitive in solutions.
9. Subtract the solvent bands before interpretation – these could be confused with bands from the sample.

Advances in computer retrieval techniques have extended the range of information available from an IR instrument by allowing comparison of an unknown spectrum with a bank of known compounds. This was always possible in the past by manually searching libraries of spectra.[9] Once the compound was classified the atlas of spectra could be searched for an identical or very similar spectrum. The advent of more efficient computers has speeded this search process. Programs widely available work by hunting through stored data to match intensities and frequencies of absorption bands. The computer will then output the best fits and the names of the compounds found. There is a wide range of spectral libraries of particular interest to life scientists. For instance, libraries for the following types of samples are currently available: proteins, peptides, enzymes, sugars, carbohydrates, fatty acids, glycerides, steroids, food additives, drugs and pharmaceuticals.

It may not always be possible by examination of the IR spectrum of a compound alone to identify it unequivocally. It is normal to use IR in conjunction with other techniques, such as chromatographic methods, mass spectrometry (MS), nuclear magnetic resonance (NMR) spectroscopy and the variety of other spectroscopic techniques.

4 QUANTITATIVE ANALYSIS

Quantitative IR spectroscopy suffers certain disadvantages when compared with other analytical techniques and it tends to be confined to specialist applications. However, there are certain applications where it is used because it is cheaper or faster. The technique is often used for the analysis of one component of a mixture, especially when the compounds in the mixture are alike chemically or have very similar physical properties (for example, structural isomers). In these instances analysis using ultraviolet/visible (UV/VIS) spectroscopy is difficult because the spectra of the components will be nearly identical. Chromatographic analysis may be of limited use because separation, of say isomers, is difficult to achieve. The IR spectra of isomers are usually quite different in the fingerprint region. Another advantage of the IR technique is that it is nondestructive and requires only a relatively small amount of sample.

4.1 Spectrum Manipulation

There are a number of techniques available to users of modern IR spectrometers which help with both qualitative and quantitative interpretation of spectra. It is usual in quantitative IR spectroscopy to use a baseline joining the points of lowest absorbance on the peak, preferably in reproducibly flat parts of the absorption line. The absorbance difference between the baseline and the top of the band is then used. A baseline construction is shown in Figure 20.

Noise in a spectrum can be diminished by smoothing. After a spectrum is smoothed it becomes similar to the result of an experiment at a lower resolution. The features are blended into each other and the noise level decreases. A smoothing function is basically a convolution between the spectrum and a vector whose points are determined by the degree of smoothing you choose to apply. Generally, you will be asked to enter a degradation factor, which will be some positive integer. A low value, say one, will produce only subtle changes, while a high value has a more pronounced effect on your spectrum.

The most straightforward method of analysis for complex spectra is difference spectroscopy. Difference spectroscopy can be carried out simply by subtracting

Figure 20 A baseline correction.

the IR spectrum of one component of the system from the combined spectrum to leave the spectrum of the other component. If the interaction between components results in a change in the structural properties of either one or both of the components, the changes will be observed in the difference spectra. The changes may manifest themselves via the appearance of positive or negative peaks in the spectrum.

Spectral subtraction can be applied to numerous applications and can be used for the data collected for solutions. In order to obtain the spectrum of a solution it is necessary to record spectra of both the solution and the solvent alone. The solvent spectrum may then be subtracted from the solution spectrum. There are two approaches – the solvent alone in the cell may be used as a reference in a double beam dispersive experiment, or the solvent spectrum may be recorded separately and then subtracted if using a single beam instrument. Figure 21, where the strong IR spectrum of water has been removed from a relatively weak spectrum of a 1% w/v solution of aspirin, illustrates how subtraction can be very useful in FTIR spectroscopy. Care must be taken when subtracting spectra. The concentration of the solvent alone is greater in than the solvent in the solution and negative peaks may appear in the regions of solvent absorption. In certain circumstances, the spectrum due to the solvent may be very intense, making simple subtraction impossible. This situation can make it difficult to investigate the sample spectrum as solvent bands may overlap with the region under investigation. In such experiments, ATR provides a suitable substitute. The nature of the ATR technique produces a less intense solvent contribution to the overall IR spectrum and so solvent spectra can be more readily subtracted from the sample spectrum of interest. Subtraction can also be applied to solid samples and is especially useful for mulls. The spectrum of the mulling agent can be subtracted, giving the spectrum of the solid only.

Spectra can also be differentiated. Figure 22 shows a single absorption peak and its first and second

Figure 21 The IR spectra of 1% w/v aspirin in water (i) and after subtraction of the water spectrum (ii). (Reproduced with permission from a Perkin-Elmer sales leaflet.)

Figure 22 A single absorption peak (i), the first derivative (ii) and the second derivative (iii).

Figure 23 A complex absorption band with first and second derivatives. (Reproduced with permission from the Perkin-Elmer application note on derivative spectroscopy.)

derivative. Derivative techniques have long been used in quantitative UV/VIS spectroscopy, the benefits of the technique being two-fold. Resolution is enhanced in the first derivative since we are looking at changes in gradient. The second derivative gives a negative peak for each band and shoulder in the absorption spectrum. The advantage of derivatization is more readily appreciated for more complex spectra and Figure 23 shows how differentiation can be used to resolve and locate peaks in an envelope. Note that sharp bands are enhanced at the expense of broad ones and this may allow selection of a peak, even when there is a broad band beneath. With modern FTIR spectrometers it is possible to apply what is known as Fourier derivation.[10] During this process the spectrum is transformed to an interferogram. It is then multiplied by an appropriate weighting function and finally it is retransformed to give the derivative. This technique provides more sensitivity.

Deconvolution is the process of compensating for the intrinsic linewidths of modes in order to resolve overlapping bands. The technique yields spectra that have much narrower bands and is able to distinguish closely-spaced features. The instrumental resolution is not increased, but the ability to differentiate spectral features can be significantly improved. This is illustrated by Figure 24, which shows a broad band before and after deconvolution has been applied. The peaks at quite close frequencies are now easily distinguished. The deconvolution technique generally involves several steps: computation of an interferogram of the sample by computing the inverse Fourier transform of the spectrum; multiplication of the interferogram by a smoothing function and by a function consisting of a Gaussian–Lorentzian band shape; Fourier transformation of the modified interferogram. The deconvolution procedure is typically repeated iteratively for best results. At iteration, the lineshape is adjusted in an attempt to provide narrower bands without excessive distortion. There are three parameters that can be adjusted to tune the lineshape. The proportion of Gaussian and Lorentzian lineshape may be altered. The scale of these components is adjusted depending on the predicted origins of the band shape. For instance, it will vary depending on whether you

Figure 24 A broad IR band before and after deconvolution.

are examining a solid or a liquid or a gas. The half-width is the width of the lineshape and is normally the same as or larger than the intrinsic linewidth (full width at half height) of the band. If the value specified is too small, the spectrum tends to show only small variations in intensity. If too large, distinctive negative side lobes are produced. The narrowing function is the degree of narrowing attempted on a scale 0–1. If specified too small, the resulting spectrum will not be significantly different from the original. If too large, the spectrum may produce false peaks as noise starts to be deconvolved.

Quantitative values for band areas of heavily overlapped bands can be achieved by using curve-fitting procedures. Many curve-fitting procedures are based on a least-squares minimization procedure. Least squares curve-fitting covers the general class of techniques whereby one attempts to minimize the sum of the squares of the difference between an experimental spectrum and a computed spectrum generated by summing the component curves. Generally, the procedure involves entering the values of the frequencies of the component bands (determined using derivatives and/or deconvolution) and then the program determines the best estimate of the parameters of the component curves. Apart from the obvious variables of peak height and width, the type of band shape needs to be considered. The class of band shape of an IR spectrum depends on the type of sample. A choice of Gaussian, Lorentzian or a combination of these band shapes is usually applied. Figure 25 illustrates the curve-fitting process.

Figure 25 Curve-fitting of overlapping IR bands.

4.2 Determination of Concentration

According to the Beer–Lambert law the absorbance of a solution is directly proportional to the thickness and the concentration of the sample (Equation 4):

$$A = \varepsilon cl \tag{4}$$

where A is the absorbance of the solution, c is the concentration and l the path length of the sample. The constant of proportionality is usually given the symbol epsilon, ε, and referred to as the molar absorptivity. The absorbance is equal to the difference between the logarithms of the intensity of the light entering the sample (I_0) and the intensity of the light transmitted (I) by the sample (Equation 5):

$$A = \log_{10}\left(\frac{I_0}{I}\right. \tag{5}$$

Absorbance is therefore dimensionless. Transmittance is defined by Equation (6) as:

$$T = \frac{I}{I_0} \tag{6}$$

The Beer–Lambert law tells us that a plot of absorbance against concentration should be linear with a gradient of εl and pass through the origin. In theory, to analyze a solution of unknown concentration, solutions of known concentration need to be prepared, a suitable peak chosen, the absorbance at this frequency measured, and a graph plotted (a calibration graph). The concentration of the compound in solution can be read, given that its absorbance is known.

However, there are a few factors which need to be considered first when taking this approach. When preparing the solutions of known concentration, the concentrations have to give sensible absorbance values – not too weak and not too intense. Choosing a suitable absorption peak is crucial. The technique should be as sensitive as possible so an intense peak should be chosen. However, often IR spectra have many, sometimes overlapping peaks. A peak isolated from others, with a high molar absorptivity is required. A further problem that sometimes arises, especially in the spectra of solid samples, is the presence of asymmetric bands. In these cases, peak height cannot be used because the baseline will vary from sample to sample. Peak area measurements should be used instead. Many FTIR spectrometers have accompanying software which can carry out these calculations. Quantitative measurements need to be carried out on absorbance spectra rather than on transmittance spectra. Thus, transmittance spectra need to be converted to absorbance spectra. Most spectrometers have this simple process incorporated into their software.

4.3 Simple Analysis

The quantitative analysis of a component in solution can be successfully carried out given that there is a suitable band in the spectrum of the component of interest. As discussed previously, the band chosen for analysis should: have a high molar absorptivity; not overlap with other peaks from other components in the mixture or solvent; be symmetrical; and give a linear calibration plot of absorbance versus concentration.

Most quantitative IR methods of analysis use the intensities of the C=O, N−H or O−H groups. The C=O stretching band is the most commonly used because it is a strong band in a spectral region relatively free of absorption by other functional groups. In addition, the carbonyl band is not as susceptible as the O−H and N−H bands to chemical change or hydrogen bonding.

Simple quantitative analysis may be illustrated using the example of aspirin dissolved in chloroform. The best peak to choose in this example is the C=O stretching band of aspirin observed at 1764 cm^{-1} because it is an intense peak and lies in a region where there is no interference from the chloroform spectrum. The next step is to draw a calibration plot of absorbance versus aspirin concentration. A series of chloroform solutions of known aspirin concentration were prepared and the IR spectrum of each solution was recorded using a 0.1 mm NaCl transmission cell. The intensity of the 1764 cm^{-1} band was measured for each solution and the results are listed in Table 5. This data can then be graphed to produce a linear plot, as shown in Figure 26. The next stage in the analysis is to determine the amount of aspirin present in a chloroform solution of unknown concentration. The IR spectrum of the unknown sample was recorded. The intensity of the 1764 cm^{-1} carbonyl band was measured and an absorbance of 0.351 was recorded. Examination of the calibration graph shows that this corresponds to a concentration of 67 mg mL^{-1}.

IR spectroscopy can be used to measure the number of functional groups in a molecule, say the number of −OH or $-NH_2$ groups. It has been found that the molar absorptivity of the bands corresponding to the group is proportional to the number of groups. That is, each group has its own intensity which does not vary drastically from molecule to molecule.

Table 5 Calibration data for aspirin solutions

Concentration (mg mL^{-1})	Absorbance at 1764 cm^{-1}
0	0.000
25	0.158
50	0.285
75	0.398
100	0.501

Figure 26 Calibration graph for aspirin solutions.

Solid mixtures can also be analyzed using IR spectroscopy. Solids are more susceptible to errors because of scattering. These analyses are usually carried out with KBr discs or in mulls. The problem here is the difficulty in measuring the path length. However, this measurement becomes unnecessary when an internal standard is used. Addition of a constant known amount of an internal standard is made to all samples and calibration standards. The calibration curve is obtained by plotting the ratio of the absorbance of the analyte to that of the internal standard, against the concentration of the analyte. The absorbance of the internal standard varies linearly with the sample thickness. The discs or mulls must be made under exactly the same conditions to avoid intensity changes or shifts in band positions. The standard must be carefully chosen and it should ideally have a simple spectrum with very few bands; be stable to heat and not absorb moisture; be easily reduced to a particle size less than the incident radiation without lattice deformation; be nontoxic, giving clear discs in a short time; and be readily available in the pure state. Some common standards used include calcium carbonate, sodium azide, naphthalene and lead thiocyanate.

4.4 Multicomponent Analysis

The analysis of a component in a complex mixture presents special problems. Quantitative analysis of a multicomponent system is illustrated by its application to

Table 6 Calibration data for drug mixture

Component	Concentration ($mg\,mL^{-1}$)	C=O stretching frequency (cm^{-1})	Absorbance
Aspirin	90	1764	0.217
Phenacetin	65	1511	0.185
Caffeine	15	1656	0.123

the simultaneous determination of aspirin, phenacetin and caffeine in tablets. These drug components can be determined by dissolving the sample in chloroform. Each of these components show distinct carbonyl bands. First the absorbances of the carbonyl bands of each of the drug components need to be measured using standard solutions. Typical results are listed in Table 6. Now the Beer–Lambert law (Equation 4) can be applied to determine the molar absorptivity for each component. Each of the standards was studied using a 0.1 mm path length NaCl transmission cell (Equations 7–9). For aspirin:

$$\varepsilon = \frac{A}{cl} = \frac{0.217}{[90\,mg\,mL^{-1} \times 0.1\,mm]} = 2.41 \times 10^{-2}\,mL\,mg^{-1}\,mm^{-1} \quad (7)$$

For phenacetin:

$$\varepsilon = \frac{0.185}{[65\,mg\,mL^{-1} \times 0.1\,mm]} = 2.85 \times 10^{-2}\,mL\,mg^{-1}\,mm^{-1} \quad (8)$$

For caffeine:

$$\varepsilon = \frac{0.123}{[15\,mg\,mL^{-1} \times 0.1\,mm]} = 8.20 \times 10^{-2}\,mL\,mg^{-1}\,mm^{-1} \quad (9)$$

Examination of the IR spectrum of the unknown sample produced under the standard sample conditions resulted in the data listed in Table 7. The concentrations of each component may be determined by once again applying the Beer–Lambert Law (Equations 10–12).

For aspirin:

$$c = \frac{A}{\varepsilon l} = \frac{0.207}{[2.41 \times 10^{-2}\,mL\,mg^{-1}\,mm^{-1} \times 0.1\,mm]} = 85\,mg\,mL^{-1} \quad (10)$$

For phenacetin:

$$c = \frac{0.202}{[2.85 \times 10^{-2}\,mL\,mg^{-1}\,mm^{-1} \times 0.1\,mm]} = 71\,mg\,mL^{-1} \quad (11)$$

Table 7 Absorbance values for unknown drug mixture

Frequency (cm^{-1})	Absorbance
1764	0.207
1511	0.202
1656	0.180

For caffeine:

$$c = \frac{0.180}{[8.20 \times 10^{-2}\,mL\,mg^{-1}\,mm^{-1} \times 0.1\,mm]} = 22\,mg\,mL^{-1} \quad (12)$$

It should be pointed out that there could be a certain degree of error in these values. There can be error due to the fact that it is difficult to select a baseline for the analysis because of overlapping peaks. Also, any nonlinearity of the Beer–Lambert law plots has been ignored, having used one value to determine the constant of proportionality above for each solution.

Alternatively, this same problem can be determined by spectral subtraction. If a sample of the additive is available, mixtures of the starting material and product can be separated by subtraction of the spectra of the mixture and additives. This is achieved by subtracting the fraction of aspirin, then phenacetin and finally caffeine from the unknown sample spectrum to null the corresponding absorptions. The subtraction factors can be read from the spectrometer computer. This second method is, of course, much faster.

Studies of the trans unsaturation in fats also provide a good illustration of multicomponent analysis. Naturally occurring vegetable fats and oils are a mixture of triglycerides of the general structure shown in Figure 27. This is a tri-ester of glycerol. The acids are long chain and can be saturated or unsaturated. The unsaturation is always present as the cis isomer. These cis bonds can be isomerized to the trans configuration during extraction or subsequent processing. For example, oxidation or partial hydrogenation can lead to isomerization. It is commercially important for labeling to determine this trans content. It is difficult to separate cis from trans isomers using other techniques such as GC and an IR method is commonly used. The IR method has the convenience of no weighing being required, nor are any

Figure 27 The molecular structure of triglycerides.

accurate volumes needed. It can therefore be used for very small samples.

The configuration of alkenes can be determined from the frequency of their C–H bending vibrations. Cis isomers absorb between 840 and 700 cm^{-1} while trans isomers absorb between 1000 and 930 cm^{-1}. This band can be used as the basis for an analytical method. It is normal to hydrolyze the triglyceride mixture to glycerol and a mixture of fatty acids, and the latter then converted to their methyl esters. It is this methyl ester mixture which is analyzed. The formulae of methyl oleate, the cis isomer and methyl elaidate, the trans isomer, are given in Figure 28. Both geometrical isomers absorb strongly at 1163 cm^{-1}, the C–O stretching frequency from the ester group. Cis isomers absorb weakly at 965 cm^{-1} while trans isomers absorb strongly at this frequency. It can be shown (Equation 13) that:

$$\%\text{trans} = K\left(\frac{A_{965}}{A_{1163}} - f\right) \qquad (13)$$

where K and f are constants, and A_{965} and A_{1163} are the absorbances of the solution at these frequencies, respectively. Note that no concentration or path length terms appear in this equation. This is the equation of a straight line of gradient K and of y-intercept, f, in a plot of % trans versus the ratio of absorbances at the two frequencies, 965 and 1163 cm^{-1}. A series of solutions of known trans composition are required, the ratio of absorbances then measured and the % trans content is then plotted against these values.

The improvement in computer technology associated with spectroscopy has also led to the expansion of quantitative IR spectroscopy. The application of statistical methods to the analysis of experimental data is known as chemometrics. There is a large amount of information now available regarding chemometrics and a detailed discussion is beyond the scope of this article. However, there are several multivariate data analytical methods

Methyl oleate
(*cis*)

Methyl elaidate
(*trans*)

Figure 28 The molecular structures of methyl oleate and methyl elaidate.

that are used for the analysis of FTIR data.[11] The most commonly used methods in IR spectroscopy are: classical least squares (CLS); inverse least squares (ILS); partial least squares (PLS); and principal component regression (PCR). CLS methods (also referred to as K-matrix methods by IR spectroscopists) use a calibration model representing the physical law that describes the variation in the spectra with composition. For example, the Beer–Lambert Law where absorbance is represented as a linear function of the component concentrations. ILS methods (also known as P-matrix methods) differ in that the data are empirically modeled without using a direct physical model. These calibration methods are not restricted to the use of the same number of components as the individual components present in the spectral region being analyzed. The newer PCR and PLS methods are two factor analysis based. Factor analysis methods are used to factor the spectral data matrix into the product of two small matrices in order to simplify the data representation. This allows a more stable solution to be achieved, compared to the use of the ILS approach.

5 APPLICATIONS

IR spectroscopy has been applied to quite a wide range of biological systems and a number of these are examined here. These include proteins, peptides, lipids, biomembranes, animal tissue, carbohydrates, pharmaceuticals, foods and plant material.

5.1 Proteins and Peptides

The IR spectra of proteins exhibit absorption bands associated with their characteristic amide group, the structural unit common to all molecules of this type (shown in Figure 29).[12] An isolated planar amide group gives rise to five in-plane modes and one out-of-plane normal mode. The in-plane modes are due to C=O stretching, C–N stretching, N–H stretching, N–H bending, O–C–N bending, while the out-of-plane mode is due C–N torsion. Characteristic bands of the amide groups of protein chains are similar to absorption bands exhibited by secondary amides in general, and are labeled amide bands. There are nine such bands, called amide A, amide B and amide I–VII, in order of decreasing frequency and these bands are summarized in Table 8. Some of these bands are more useful for conformation

Figure 29 The amide group of proteins.

Table 8 Characteristic IR amide bands of proteins

Designation	Approximate frequency (cm^{-1})	Nature of vibration
A	3300	N–H stretching in resonance with
B	3110	with overtone (2 × amide II)
I	1653	80% C=O stretching; 10% C–N stretching; 10% N–H bending
II	1567	60% N–H bending; 40% C–N stretching
III	1299	30% C–N stretching; 30% N–H bending; 10% C=O stretching; 10% O=C–N bending; 20% methyl-CH_3 stretching
IV	627	40% O=C–N bending; 30% methyl-CH_3 stretching and 30% other
V	725	N–H bending
VI	600	C=O bending
VII	200	C–N torsion

studies than others and the amide A, amide I and amide II bands have been the most frequently used. Knowledge of peptide bond vibrations is based mainly on normal coordinate calculations using *N*-methylacetamide as a model compound.

The most useful IR band for the analysis of the secondary structure of proteins in aqueous media is the amide I band, occurring between approximately 1700 and 1600 cm^{-1}.[13] The amide I band represents (80%) C=O stretching vibration of the amide group coupled to the in-plane N–H bending and C–N stretching modes. The exact frequency of this vibration depends on the nature of hydrogen bonding involving the C=O and N–H groups and this is determined by the particular secondary structure adopted by the protein. Proteins generally contain a variety of domains containing polypeptide fragments in different conformations. As a consequence, the observed amide I band is usually a complex composite, consisting of a number of overlapping component bands representing helices, β-structure, turns and random structures.

The amide II band represents mainly (60%) N–H bending, with some C–N stretching (40%). Like the amide I band, it is possible to split the amide II band into components depending on the secondary structure of the protein. The position of the amide II band is sensitive to deuteration, shifting from around 1550 cm^{-1} to a frequency of 1450 cm^{-1}. The amide II band of the deuterated protein overlaps with the H–O–D bending vibration, making it difficult to obtain information about the conformation of this band. However, the remainder of the amide II band at 1550 cm^{-1} may provide information about the accessibility of solvent to the peptide backbone. Hydrophobic environments or tightly ordered structures, such as α-helix or β-sheet, reduce the chance of exchange of the amide N–H proton.

Secondary amides in the trans configuration exhibit two characteristic bands at about 3300 cm^{-1} and 3100 cm^{-1}, while those in this configuration show two bands at about 3200 cm^{-1} and 3100 cm^{-1}. The band at 3300–3200 cm^{-1} is the amide A band and is due to the stretching mode of the N–H bond which is hydrogen bonded. The amide B is at 3100 cm^{-1} and is due to the Fermi resonance of the N–H stretching vibration with the overtone of the amide II vibration for the trans configuration and with the combination of the C–O stretching and N–H in-plane bending vibrations for the cis configuration. The amide A and B bands are very sensitive to hydrogen bonding, but because of the mixed nature of these modes correlations between frequency shifts and hydrogen bonding are more complex than would be the case for an unperturbed N–H fundamental.

The amide III and the amide VII bands have not been studied as extensively as the amide A, B, I and II modes. The amide III and amide IV vibrations are complex in-plane modes with no more than about 40% of the potential energy associated with any single internal displacement coordinate. The amide IV and VII vibrations cannot even be said to be localized in the amide group and normal coordinate analysis of system containing several repeat units are necessary to interpret their relationship to structure.

Of the low frequency modes, the amide V vibration has been the most useful in structural investigations since it involves N–H out-of-plane bending and depends considerably on the backbone conformation. The amide V mode represents N–H out-of-plane bending and depends considerably on the backbone conformation. The band appears at around 600 cm^{-1} for an α-helical conformation, at around 650 cm^{-1} for unordered structures and at around 700 cm^{-1} for β-structure.

The amide IV, VI and VII modes have not yet been studied in detail and little information is available regarding their dependence on conformation. The amide IV band represents 40% O=C–H bending and 30% methyl–C stretching, the amide VI represents C=O out-of-plane bending. The amide VII band represents C–N torsion. Both of these modes have low intensities, making information difficult to obtain. Also, information is difficult to extract about the amide VII band because of its low frequency.

The amide III band is heavily mixed, representing 30% C–N stretching, 30% N–H in-plane bending and 20% methyl–C stretching. The amide III mode is also sensitive to secondary structure, but also gives rise to a very weak IR band at about 1300 cm^{-1}. Due to different selection rules, the amide VIII band is much stronger in the corresponding Raman technique, making Raman

Table 9 The characteristic frequencies of amino acid side chains

Amino acid	Frequency (cm^{-1})	Assignment
Alanine	1465	CH_2 bending
Valine	1450	CH_3 asymmetric bending
Leucine	1375	CH_3 symmetric bending
Serine	1350–1250	O–H deformation
Aspartic acid	1720	C=O stretching

	1415	CO_2^- symmetric stretching
Asparagine	1650	C=O stretching
Glutamine	1615	NH_2 bending
Lysine	1640–1610, 1550–1485	NH_3^+ deformation
	1160, 1100	NH_3^+ rocking
Phenylalanine	1602, 1450, 760, 700	Ring vibrations
Tyrosine	1600, 1450	Ring vibrations

spectroscopy a more suitable technique for studying this vibrational mode.

In general, a spectrum can only be properly analyzed if all the absorption bands are considered because there are no isolated vibrations involving only particular groups of atoms. However, for complex molecules it is possible to draw conclusions from the analyses of selected bands if the corresponding vibrations can be regarded as localized and this is true for many of the characteristic amide bands. It should be pointed out that the characteristic amide bands are not the only bands to appear in the spectra of proteins or simple model compounds. There are bands associated with C–H, C–N and C–C linkages in the spectra of model compounds.

In addition, the IR contributions of the side chains of the amino acids which constitute the protein must also be considered. Amino acid side chains exhibit IR modes that are often useful for investigating the local group in a protein. Fortunately these contributions have been found to be small in D_2O compared to the contributions made by the amide I band. It is also important to be aware of the location of such modes as they may be confused with amide vibrations. But the arginyl residue is the only residue which makes a significant contribution in the 1700–1600 cm^{-1} region. However, even the bands at 1586 and 1608 cm^{-1} due to the arginyl residue do not contribute greatly compared to the amide I contributions. The characteristic side chain IR frequencies of amino acids are summarized in Table 9.

Quantitative analysis of the secondary structures of polypeptides may be carried out. The amide I band of proteins and peptides consists of a series of overlapped component bands due to the secondary structures present in such molecules. Resolution enhancement of the amide I band allows the identification of various structures present in a protein or peptide. Derivatives and deconvolution can be used to obtain such information. Figure 30 illustrates the use of these methods to analyze the amide I mode of a peptide. However, simply measuring the peak heights of the resulting spectra does not provide an accurate measure of the proportion of secondary structure. In Fourier deconvolved spectra the band shapes are distorted and the extent of this distortion depends on the widths of the component bands and the parameters use to compute the deconvolved spectra, so the resulting peak heights are complex functions of a number of parameters. Similarly, the peak heights in the derivative spectra

Figure 30 The original, deconvolved and derivative spectra of a peptide amide I band.

cannot be used as a quantitative measure because they are functions of both intensities and the widths of the original bands. The best method used for the estimation of protein secondary structure involves band-fitting the amide I band. The parameters required, the number of component bands and their positions, are obtained from the resolution enhanced spectra. The fractional areas of the fitted component bands are directly proportional to the relative proportions of structure that they represent. The percentages of helix, β-structure and turns are estimated by addition of the areas of all the component bands assigned to each of these structures and expressing the sum as a fraction of the total amide I area. The assumption is made that the intrinsic absorptivities of the amide I bands corresponding to different structures are identical.

IR spectroscopy has been used in a large number of studies of proteins in a range of environments. Some examples of the proteins analyzed are listed in Table 10, which details the deconvolved amide I frequencies and secondary structure assignments made for a series of proteins in D_2O.[14] These assignments are based on the fact that the secondary structures of these globular proteins have been very well characterized by X-ray crystallography. The characteristic frequencies of the secondary structures of proteins have also been estimated from normal coordinate calculations on model peptides and proteins of known structure.[13] The frequencies are summarized in Table 11. These assignments are by no means exact and some bands may appear outside these ranges for some proteins, particularly when solvent interactions are considered.

An example of the quantitative approach to protein analysis is illustrated by Figure 31 which shows the amide I band of the enzyme lysozyme in D_2O. The amide I band of this protein shows nine component bands and the relative

1684	2
1693	<1

areas of these components are listed in Table 12. The components may be assigned to the various types of secondary structures. The bands at 1623 and 1632 cm^{-1} are characteristic of β-structure, as is the band at 1675 cm^{-1}. The bands at 1667, 1684 and 1693 cm^{-1} occur at frequencies characteristic of turns and bends. The band at 1610 cm^{-1} is due to arginyl side chain vibrations and the 1640 cm^{-1} band may be assigned to random coil. The two remaining bands at 1648 and 1657 cm^{-1} are due to the presence of α-helix. Usually in protein IR spectra only one component due to α-helix is observed. However, X-ray data indicates the presence of two types of helix in lysozyme: α-helix and 3-turn helix. These different helices vibrate at different frequencies. The 1657 cm^{-1} is assigned to α-helix, while the 1648 cm^{-1} band is due to 3-turn helix. These assignments give a quantitative estimate of 48% helix, 23% β-structure, 13% turns and 16% random coil in lysozyme.

Peptides are often derived from the larger proteins, and a similar quantitative approach can be applied to these molecules. However, their small size must be taken into account when applying such methods. Small peptides are not necessarily capable of producing the same secondary structures observed in proteins. The CiT4 peptide is derived from a nervous system protein and consists of a sequence of 26 amino acids. The amide I band of CiT4 peptide in D_2O has been deconvolved and curve-fit and the results are illustrated in Figure 32. Table 13 lists the wavenumber and the fractional area of each component of the amide I band of CiT4 in D_2O. The major component in Figure 32 is observed at 1644 cm^{-1}, contributing to 73% of the total amide I band area. This frequency is characteristic of random coil in proteins and peptides. Two smaller component bands appear at 1664 and 1674 cm^{-1}, respectively, and both can be attributed to turns and bends in the peptide structure. The weak component at 1617 cm^{-1} is at a frequency associated with arginine side chain contributions.

The solvent environment in which proteins and peptides are recorded affects the secondary structures observed for these molecules. For instance, the solvent trifluoroethanol (TFE) is more polar than water. The FTIR spectrum of the CiT4 peptide in TFE/D_2O is shown in Figure 33. The frequency and the fractional area of

each component of the amide I band of CiT4 in TFE solution are listed in Table 14. There are significant changes observed to the amide I band of CiT4 in the presence of TFE. There is a notable change in the shape of the amide I band and six component bands are observed. The small component at 1610 cm^{-1} occurs in the frequency range normally attributed to side chain contributions. The components at 1623 and 1637 cm^{-1} are assigned to low-frequency β-structure, with a high-frequency component of β-structure also observed at 1675 cm^{-1}. These bands contribute to 43% of the total band area. The component in Figure 33 observed at 1655 cm^{-1}, contributing to 21% to the total amide I band area, is assigned to α-helix. The remainder of the components in Figure 33 at 1661 and 1689 cm^{-1} are assigned to turns and bends in the peptide secondary structure. Analysis of the spectrum of CiT4 in TFE/D_2O solution indicates differences in the secondary structure of the peptide when compared to that observed for the peptide in the pure aqueous solution. On addition of TFE, a more structured conformation of CiT4 is indicated. Notably α-helical structure and β-structure appear to be formed in the less polar environment provided by TFE. Thus, a change in environment, in this case solvent, can cause notable changes to a peptide conformation observable using IR spectroscopy.

IR techniques can also be used to study protein adsorption onto surfaces. For example, a flow-through ATR cell can be used ex vivo with flowing blood. Blood–surface interactions are of great importance when medical polymers, such as those used in heart valves and artificial organs, are implanted into the body. When polymers come into contact with blood, complex reactions take place and can result in the formation of a blood clot. IR analysis has shown in ex vivo studies of dogs that during the early stages the proteins albumin and glycoprotein are present. Immediately after this observation increased amount of fibrinogen appear. As the adsorption process continues, albumin is replaced by other proteins until a blood clot is formed.

5.2 Lipids

Many of the lipids found in nature contain phosphorus and are classed as phospholipids. One class of phospholipid are the phosphoglycerides and the general structure of this type of lipid is illustrated in Figure 34. Phospholipids are organized in lipid bilayers of about 40–80 Å in thickness, where the polar head group points towards the aqueous phase and hydrophobic tails point towards the tails of a second layer. The chains can be in an all trans conformation which is referred to as the gel phase. A liquid crystalline phase is obtained when the chain also contains gauche C–C groups.

The IR spectra of phospholipids can be divided into spectral regions which originate from molecular vibrations of the hydrocarbon tail, the interface region and the head-group.[15] The major IR modes due to phospholipids are summarized in Table 15. The hydrocarbon tail gives rises to acyl chain modes. The most intense vibrations in the IR spectra of lipid systems are the CH_2 stretching vibrations. These give rise to bands in the region 3100 to 2800 cm^{-1}. The CH_2 asymmetric and symmetric stretching modes at 2920 and 2851 cm^{-1}, respectively, are generally the strongest bands in the lipid spectra. The frequencies of these bands are conformation-sensitive and respond to changes of the trans/gauche ratio in the acyl chains. This is also the case for the vibrational modes due to the terminal CH_3 groups at 2956 cm^{-1} (asymmetric stretching) and 2873 cm^{-1} (symmetric stretching). The C=C–H stretching bands due to unsaturated acyl chains are found at 3012 cm^{-1}. The bands due to methylene and methyl groups occur in the 1500–1350 cm^{-1} region. At around 1470 cm^{-1} there are bands due to CH_2 bending and the number and frequency of these bands are dependent on acyl chain packing and conformation. While the asymmetric

1485	$(CH_3)_3N^+$ asymmetric bending
1473, 1472, 1468, 1463	CH_2 scissoring
1460	CH_3 asymmetric bending
1405	$(CH_3)_3N^+$ symmetric bending
1378	CH_3 symmetric bending
1400–1200	CH_2 wagging band progression
1228	PO_2^- asymmetric stretching
1170	CO−O−C asymmetric stretching
1085	PO_2^- symmetric stretching
1070	CO−O−C symmetric stretching
1047	C−O−P stretching
972	$(CH_3)_3N^+$ asymmetric stretching
820	P−O asymmetric stretching
730, 720, 718	CH_2 rocking

deformation modes of the CH_3 group are obscured by the scissoring bands, the symmetric deformation mode appears at 1378 cm^{-1}. The polymethylene chains show a series of bands in the region 1380–1180 cm^{-1} but these are obscured in the spectra of phospholipids because they overlap with the strong PO_2^- asymmetric stretching band around 1228 cm^{-1}. There is also a series of CH_2 rocking bands in the 1150–700 cm^{-1} region. The most intense band of this group is at 720 cm^{-1} and overlaps with a strong H_2O band, so it is necessary to observe it in D_2O. Deuteration of lipids result in C−D stretching frequencies in the 2000–2300 cm^{-1} region, a region free from interfering absorption bands. As for the C−H stretching bands, the C−D stretching bands are sensitive to the conformation and the trans/gauche ratio of the deuterated acyl chain segments. Bands around 2195 and 2090 cm^{-1} are due to the CD_2 asymmetric and symmetric stretching vibrations, respectively. Bands at 2212, 2169 and 2070 cm^{-1} arise from the CD_3 group. Deuteration also simplifies the fingerprint region of the IR spectra as the methylene wagging and rocking-twisting band progressions disappear from their usual position in the 1400–700 cm^{-1}.

Spectral modes arising from the head-group and interfacial region also provide useful information.[16] The most useful IR bands for studying the interfacial region of lipid assemblies are the ester group vibrations, particularly the C=O stretching bands in the 1750–1700 cm^{-1} region. In diacyl lipids this region consists of at least two bands originating from the two ester carbonyl groups. A band at 1742 cm^{-1} is assigned to the C=O mode of the *sn*-1 chain with a trans conformation in the carbon–carbon bond adjacent to the ester grouping, while the 1728 cm^{-1} C=O frequency of the *sn*-2 chain suggests the presence of a gauche band in that position. The frequency difference observed reflects the structural inequivalence of the chains, with the *sn*-1 chain initially extending in a direction perpendicular to the *sn*-2 chain and then developing a gauche bend in order to render the two chains parallel. For example, the C=O stretching region of the spectrum of the lipid phosphatidylserine (PS) is shown in Figure 35. The band at 1624 cm^{-1} is due to the asymmetrical CO_2^- stretching vibration of PS. The band at 1737 cm^{-1} is broad, consisting of two ester C=O stretching bands at 1742 and 1728 cm^{-1} and a small band at 1701 cm^{-1} which is assigned to a hydrogen-bonded carbonyl group. The higher frequency band at 1742 cm^{-1}, associated with the *sn*-1 chain of PS is the more intense band, indicating that a trans conformation of the chain about the C−C bond is favored.

The choline, ethanolamine and serine groups have characteristic modes. The CH_3 asymmetric stretching modes of the $(CH_3)_3N^+$ group are around 3040 cm^{-1} and are out of the range of the acyl chain CH_3 bands. The corresponding methyl bending vibrations of the choline group occur at higher frequencies, compared to those of the acyl chain methyl groups. The C−N stretching bands are found between 1040 and 800 cm^{-1}. There are also several characteristic phosphate group vibrations. There are strong bands due to the P=O stretching vibration: an asymmetric PO_2^- stretch around 1228 cm^{-1} and a symmetric PO_2^- stretch around 1085 cm^{-1}. There are P−O stretching modes in the region 900–800 cm^{-1}, but these are obscured by strong water absorption in this region.

In certain phospholipid membranes which contain unsaturated acyl chains, the typical lamellar liquid crystalline phase converts to a micellar nonlamellar phase

Figure 35 The C=O stretching region of PS in D_2O.

Figure 36 The temperature dependence of the symmetric CH_2 stretching band of PE.

upon heating.[17] Such a thermally-induced transition involves a major structural rearrangement. Temperature studies of the IR spectra of phospholipids provide a sensitive means of studying such transitions in lipids. Figure 36 shows the temperature dependence of the frequency of the symmetric CH_2 stretching band in the spectra of lipid membranes obtained from phosphatidylethanolamine (PE). The increasing frequency with temperature indicates an increasing concentration of gauche bands in the acyl chains and this leads to the formation of the nonbilayer phase at higher temperatures. Figure 36 shows a frequency shift of about $2\,cm^{-1}$ at 18 °C and this is associated with the gel to liquid crystal phase transition. An additional frequency shift of approximately $1\,cm^{-1}$ at 50 °C is associated with a transition to the micellar phase. Both these transitions have been observed to be reversible.

Quantitative IR analysis can be carried out on blood serum to determine the relative amounts of lipid present.[18] Triglycerides, phospholipids and cholesteryl esters are the classes of lipid which occur in blood serum. These compounds occur naturally in concentrations which make IR analysis attractive, and the necessary preliminary separation is simple. These classes of compounds can be characterized using IR spectroscopy by their carbonyl bands. The peak maxima are:

triglyceride $1742\,cm^{-1}$
phopholipid $1737\,cm^{-1}$
cholesteryl ester $1723\,cm^{-1}$.

However, the carbonyl peaks are heavily overlapped and these are too close to allow analysis by three simultaneous equations, but a least-squares method can be used to separate the components. The concentrations of these lipid components are usually in the range 0.03–0.3% in human blood, and standard solutions can be prepared in chloroform.

5.3 Biomembranes

FTIR spectroscopy is particularly useful for probing the structure of membrane proteins.[17] Until recently a lack of adequate experimental techniques has been the reason for the poor understanding of the secondary structure of most membrane proteins. X-ray diffraction requires high quality crystals and these are not available for many membrane proteins. Circular dichroism (CD) has been widely used for studying the conformation of water-soluble proteins, but problems arise for its use for membrane proteins. The light scattering effect may distort CD spectra and lead to substantial errors in their interpretation. Also, the reference spectra used for the analysis of CD spectra are based on globular proteins in aqueous solution and may not be applicable to membrane proteins in the hydrophobic environment of lipid bilayers. IR spectroscopy is largely unaffected by the aforementioned problems. The technique can be used to study the secondary structure of proteins both in their native environment, as well as after reconstitution into model membranes. IR spectroscopy offers several advantages for studies of protein–lipid interaction. Information about lipid conformation and protein secondary structure from the same sample can be obtained in a single experiment.

Myelin basic protein (MBP) is a major protein of the nervous system and has been studied using FTIR spectroscopy in both aqueous solution and after reconstitution in myelin lipids.[19] The amide I band of MBP in D_2O solution (deconvolved and curve-fit) illustrated in Figure 37. The amide band shows a small band at $1616\,cm^{-1}$ which occurs at a frequency normally attributed to amino acid side chain contributions. The largest component band observed at $1647\,cm^{-1}$ is assigned to random coil and accounts for 86% of the total band area. The remaining component band at $1671\,cm^{-1}$ is assigned to turns and bends in the protein. Table 16 lists the frequency and the fractional area of each component of the amide I band of MBP in D_2O. The FTIR spectrum of MBP protein after reconstitution in myelin with all proteins removed was also recorded. The results of deconvolution and band-fitting the amide I band of MBP in myelin are shown in Figure 38. The frequency and the fractional area of each component of the amide I band of MBP in myelin are listed in Table 17. There are dramatic changes

observed to the amide I band of MBP when the protein is complexed with myelin. In Figure 38 the two small components at 1606 and 1616 cm^{-1} occur in the frequency range attributed to side chain contributions. The appearance of the band at 1624 cm^{-1} indicates the presence of water-bonded β-structure. Also, the component at 1634 cm^{-1} is assigned to β-structure, with a high-frequency component due to β-structure observed at 1675 cm^{-1}. These bands

Table 17 Analysis of the amide I band of MBP in myelin

Frequency (cm^{-1})	Relative area (%)
1624	8

1642	9
1651	22
1663	14
1675	11
1686	3

contribute to 40% of the total band area. This estimation indicates that a notable amount of β-structure is formed when the results are compared to those obtained for MBP in D_2O where no β-structure was observed. The component at 1651 cm^{-1}, contributing to 28% of the total amide I band area, is assigned to α-helix in the protein. Thus, reconstitution of MBP in myelin produces a significant amount of α-helix in the protein in the predominantly lipid environment. Again, none of this type of structure was observed for the protein in an aqueous environment. The small component at 1642 cm^{-1} appears at a frequency normally attributed to random coil. The remainder of the components in Figure 38 at 1663 and 1686 cm^{-1} are assigned to turns and bends in the protein. Thus, the importance of the conditions in which biological molecules are examined in the IR needs to be emphasized. It is observed here with the example of MBP that the protein that this protein is very sensitive to the surroundings. The latter lipid environment more closely mimics the native environment, and thus presumably gives a far better indication of the native structure.

5.4 Animal Tissue

In recent years IR spectroscopy has been used in clinical analysis.[20,21] In particular, high-pressure (pressure-tuning) IR spectroscopy has been developed as a successful technique for the evaluation of malignancy in human tissues. The pressure dependence on parameters such as frequency, intensity and band shape can provide further information about the structural changes associated with malignancy. For example, it is possible to detect cervical cancer arising from a premalignant state termed dysplasia by using IR band differences among normal, dysplastic and malignant cervical cells. A study of the pressure dependence of the frequencies of bands indicates that there are extensive changes in the degree of hydrogen bonding of phosphodiester groups of nucleic acids and the C–OH groups of proteins. Pressure studies also indicate changes in the degree of disorder of methylene chains of lipids in the malignant tissue. The IR spectra of tissue

Figure 40 The FTIR microscopic spectrum of skin before and after treatment with emollient followed by washing. (Reprinted from R.G. Messerschmidt, M.A. Harthcock (eds.), *Infrared Microspectroscopy: Theory and Applications*, 1998 by courtesy of Marcel Dekker, New York.)

samples with dysplasia demonstrate the same changes to a lesser degree than those observed for the cancer samples. Figure 39 shows the pressure dependence of the CH_2 bending mode frequency of the methylene chain of lipids for both normal and malignant tissue. Pressure increases this frequency because it induces ordering of the methylene chains in the lipid bilayers, thus increasing interchain interactions. In malignant cervical tissue, pressure induces a smaller shift in the frequency of this mode compared with normal tissue. The difference indicates that in cervical cancer the methylene chains of lipids are more disordered than in normal cervical tissue.

Skin samples are often used to study the interactions of various chemical mixtures, such as lotions, with living tissue.[7] FTIR microscopy offers a valuable tool for these types of analyses as living skin is relatively expensive and difficult to obtain. This technique has been used to study a piece of living skin treated with a conditioning emollient. The sample was then subjected to various washes. Figure 40 shows the FTIR microscopic spectrum of the skin ($200 \times 200\,\mu m$) after treatment with the emollient followed by washing. Figure 40 also shows the spectrum of a piece of control skin. Comparison of the spectra indicates the appearance of a band near $730\,cm^{-1}$ due to the long chain aliphatic hydrocarbon component of one of the lotions constituents. Also, there is the notable appearance of a band at $1040\,cm^{-1}$ due to hydroxy C–O stretching related to one of the active ingredients in the emollient. This example demonstrates how an IR microscope can be utilized as a probe for measuring the presence of chemicals on skin.

5.5 Carbohydrates

The structure of monsaccharides has been successfully studied using IR spectroscopy. For example, IR spectroscopy can be used to clarify the structure of the simple sugar glucose. Although glucose exists almost entirely in the cyclic form, in solution it appears to be in equilibrium with a minute amount of the noncyclic form. Figure 41 shows these glucose structures. IR spectroscopy has been used to show that the acyclic form of this sugar is not present to any appreciable extent because it equilibrates to give different cyclic forms. The acyclic form of the glucose has an aldehyde group present and should

Figure 41 Glucose structures.

Figure 42 Nucleotides and nucleic acids.

Figure 43 The structure of GMP.

obviously produce a significant carbonyl absorption. As the spectrum does not show a carbonyl absorption it is clear that the acyclic form cannot be present.

Nucleic acids are vital molecules which carry the genetic code and are responsible for its expression by protein synthesis. The two types of nucleic acids are deoxyribonucleic acids (DNA) and ribonucleic acids (RNA). The components of nucleic acids can be obtained by hydrolysis. Partial hydrolysis of a nucleic acid produces nucleotides, which consist of a base, a sugar and a phosphate group. Nucleotides are monomers for nucleic acid polymers, illustrated in Figure 42. Raman spectroscopy has been used extensively for the investigation of nucleic acids, but it is also possible to study these molecules using IR spectroscopy. The IR spectra of nucleic acids can be divided into the modes due to the constituent base, sugar and phosphate groups. One of the principal deoxyribonucleotides is deoxyguanosine monophosphate (GMP), the structural formula of which is shown in Figure 43. The major IR modes of GMP are listed in Table 18.[22]

5.6 Pharmaceuticals

IR spectroscopy has been extensively used in both qualitative and quantitative pharmaceutical analysis.[23] There is widespread use of FTIR for the identification

Table 18 The major IR bands of GMP

Frequency (cm^{-1})	Assignment

of drugs, excipients and the raw materials used in the manufacture of pharmaceuticals. FTIR spectroscopy has been used to differentiate the structures of penicillins. The general structure of penicillins is shown in Figure 44, where the R group depends on the nature of the particular penicillin. Table 19 lists the major characteristic IR bands of penicillins recorded in D_2O. Quantitative analysis can be readily performed using the intensity of the β-lactam carbonyl stretching band.

GC/IR is an appropriate technique for drug analysis as it can be used for isomer separation or contaminant detection.[24] The technique is emerging as a complementary method to GC/MS, which is generally accepted as the most definitive method for identification of drugs of abuse in urine, for instance. Amphetamines are one class of drug

which have been successfully differentiated using GC/IR. Amphetamines are structurally similar molecules which can be easily misidentified. In particular, there are some common 'designer drug' derivatives of amphetamine. However, although such similar compounds cannot be differentiated by their mass spectra, there are prominent differences in their IR spectra. Figure 45 illustrates the FTIR spectrum of an amphetamine derivative detected using GC/IR.

5.7 Foods

Near-IR spectroscopy has proved to be a very useful technique for the investigation of foods.[25] The major IR modes in this region in the spectra of foods are due to O–H, N–H and C–H groups. These groups appear due to the presence of proteins, carbohydrates and fats in food. Near-IR has been used in a wide range of studies in food analysis, including the protein content of wheat and meat, analysis of fiber, and oil in mayonnaise. Figure 46 shows the near-IR spectrum of dehydrated tomato soup and this illustrates the modes of common food components.

Wine analysis is also feasible with near-IR spectroscopy. Near-IR provides a relatively straightforward method of analyzing ethanol in wine. The O–H bond in ethanol produces a near-IR mode that is easily distinguished from the O–H mode of water. In the 1980s the wine industry was troubled by several cases of adulteration using diethylene glycol and methanol. Methanol is easily distinguished from ethanol in the near-IR. Figure 47 illustrates that a 1% addition of methanol to a wine sample is easily distinguished from a 1% addition of ethanol. Thus, near-IR spectroscopy has potential as a method for the routine screening of wine.

Near-IR is also an effective approach to the analysis of artificial sweeteners. The near-IR spectrum of saccharin is shown in Figure 48. As aromatic compounds are not very common in food products so modes due to those

compounds are useful. Although saccharin is found at low concentrations in foods, it is normally added as a concentrated solution and this can be monitored by near-IR measurements in the presence of other ingredients.

5.8 Plant Material

FTIR spectroscopy has emerged as a suitable tool for the investigation of plant material.[7] For instance,

Figure 48 The near-IR spectrum of saccharin. (Reproduced by permission of the Royal Society of Chemistry from C.S. Creaser, A.M.C. Davies (eds.), *Analytical Applications of Spectroscopy*, Royal Society of Chemistry, Cambridge, 1988.)

it can be used to examine the quality of animal food, such as alfalfa. There is a relationship between the quality of alfalfa as a food supplement and the plant age. IR microscopy can be used to compare an old plant with a young plant. Figure 49 shows the spectra of an old and young leaf (both $100 \times 100\,\mu m$). At first sight it is difficult to discern any major differences between these spectra. However, spectral subtraction illustrates some important differences. Figure 50 shows the difference spectrum obtained by subtracting the spectrum of the young plant from that of the older plant. Positive bands indicate a higher relative concentration in the older leaf and negative bands indicate a high concentration in the younger plant. A carbonyl band near $1700\,cm^{-1}$ indicates a high

concentration in the older plant. A higher protein content in the young plant is suggested by the negative amide I and amide II bands at 1650 and $1545\,cm^{-1}$, respectively. Thus, Figure 50 tells us that there is a significant difference in the cellulosic nature of the two samples, with the older plant having a higher relative cellulose content.

ABBREVIATIONS AND ACRONYMS

ATR	Attenuated Total Reflectance
CD	Circular Dichroism
CLS	Classical Least Squares
DAC	Diamond Anvil Cell
DRIFT	Diffuse Reflectance Infrared Technique
FTIR	Fourier Transform Infrared
GC	Gas Chromatography
GC/IR	Gas Chromatography/Infrared
GC/MS	Gas Chromatography/Mass Spectrometry
GMP	Deoxyguanosine Monophosphate
ILS	Inverse Least Squares
IR	Infrared
MBP	Myelin Basic Protein
MIR	Multiple Internal Reflectance
MS	Mass Spectrometry
NMR	Nuclear Magnetic Resonance
PCR	Principal Component Regression
PE	Phosphatidylethanolamine
PLS	Partial Least Squares
PS	Phosphatidylserine
PTFE	Polytetrafluoroethylene
TFE	Trifluoroethanol
TGA	Thermogravimetric Analysis
UV/VIS	Ultraviolet/Visible

Mass spectrometric methods may serve as powerful analytical methods in life sciences and medicine. Mass spectrometry (MS) is comparable in sensitivity to techniques based on chromatography or electrophoresis but has superior resolution. Although there are a number of suitable ionization methods, allowing the analysis of biological molecules that are of high molecular weight and low volatility, there are mainly two ''soft-ionization'' techniques that confer only a minimum of degradation of the analyte: MALDI (matrix-assisted laser desorption/ionization) and ESI (electrospray ionization).

The following article provides a short overview on the advantages and drawbacks of MALDI analysis of biological samples. Whereas most applications of MALDI are in the field of protein analysis, the analyses of carbohydrates and lipids are also comprehensively discussed. It is shown that MALDI is a useful tool especially in the field of lipid analysis, whereas with carbohydrate analysis, still a number of problems have to be solved. MALDI is a rapid and very sensitive (from the low picomolar to the attomolar range) tool that tolerates high amounts of impurities (in contrast to ESI), which are typically present in biological samples. A further advantage is that mainly singly charged ions are formed; this enables MALDI to be applied even to the analysis of crude mixtures although ion yields may differ significantly in dependence on the molecules of interest. In comparison with ESI, MALDI detects compounds of higher molecular weights more sensitively, whereas ESI is more suitable for labile compounds. Therefore, the combination of both methods is, in many cases, the ideal solution for a number of analytical problems.

1 INTRODUCTION

Chemists and biochemists were searching for a long time for a simple method to accurately and sensitively determine the molecular masses of naturally occurring biopolymers such as proteins or polysaccharides. Established methods in this field today are chromatographic techniques (gel filtration) or gel electrophoresis (sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS/PAGE)). However, both methods are relatively time-consuming and do not provide high mass accuracy.[1]

MS is superior to all other techniques for mass resolution. Highlights in the development of MS, showing its unusual high mass resolution, are the exact determination of atomic weights and the discovery of new isotopes of a given element. The main problem in MS, however, is that the sample has to be evaporated to form intact, isolated, ionized molecules in the gas phase.

Unfortunately, because of their high polarity and often extremely high molecular weight (and the resulting low volatility), most biopolymers cannot be ionized by the ''classical'' electron impact (EI) mass spectroscopy method,[2] which is widely used for the analysis of small molecules with molecular weights up to about 1000 Da.[3] In this approach, most information is obtained from typical fragmentation patterns and the intensity of the molecular ion is often very weak or is even completely absent for biopolymers.

Since the mid-1970s, new volatilization and ionization techniques that also allow the analysis of high-molecular-weight polar biopolymers have been developed. Although mass spectrometers were already being manufactured during or just after World War II by several companies, some time passed until the EI technique was extended with the invention of the field ionization (FI) and field desorption (FD) techniques in which the sample was ionized by a strong electric field gradient, resulting in less fragmentation.[4] Although the molecular masses of polymers that could be analyzed by this technique were rather low, this was the initial step toward making MS also suitable for biological samples. At much the same time, the potential of the technique of chemical ionization (CI) (discovered by Thompson in 1913) was recognized. In this approach, the analyte is ionized through its reaction with gas molecules (e.g. ammonia).[5] This technique is much more gentle than EI and generates less fragment ions, allowing the determination of the molecular weight by the detection of the molecular ion. Secondary ion mass spectrometry (SIMS),[6] plasma desorption (PD) mass spectrometry,[7] and laser desorption (LD) mass spectrometry[8] soon followed. Fast atom bombardment (FAB) is very successful for the analysis of highly polar, low-volatility compounds but has the disadvantage of producing a large amount of fragmentation.[2] An overview of the most important ionization techniques, their benefits, and drawbacks is given in Table 1.

Two rather new ''soft-ionization'' techniques[9] (i.e. with only a very small amount of fragmentation) are ESI[2,10] and MALDI,[11] which now are successful MS methods since both are suitable for the analysis of large biopolymers. A further advantage is the rather simple and less-expensive experimental design allowing simple time-of-flight (TOF) instruments to be used.[3] Therefore, compared to classical instruments, such modern mass spectrometers are rather small.

In 2002, the inventors of these techniques, Tanaka et al.[12] and Fenn et al.[13] were awarded the Nobel Prize for the development of MALDI and ESI, respectively.[14] It should be noted that in the very first ''MALDI'' study, ultrafine cobalt powder was used as the ''matrix''.[12] Nowadays, however, organic matrix compounds are nearly exclusively used for many different reasons. The latter approach was developed by Franz Hillenkamp and Michael Karas in Germany and was published already in 1988.[15]

Although ESI and MALDI yield comparable (often complementary) information, this article mainly deals with the application of matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI/TOF MS) for the analysis of biologically relevant samples. MALDI/TOF is primarily established in the field of protein[16–18] and peptide analysis.[19] Terms such as ''proteomics''[20] or even ''peptidomics''[21] are nowadays widely established, although their exact definition still remains to be specified. Nevertheless, its applicability for carbohydrate[22,23] and lipid analysis[24,25] is also described and compared with other MS methods.

1.1 What is Matrix-assisted Laser Desorption/Ionization Time-of-flight Mass Spectrometry

A comprehensive description and the theoretical basics of classical MS and the corresponding experimental equipment are discussed in detail in other articles in this Encyclopedia. Here, only a few comments on the special features of MALDI/TOF MS are given. This is one of the fastest and most accurate methods to determine a number of polymer (mainly biopolymers) characteristics, especially their molecular weight and the corresponding weight distribution.[16]

MALDI is based (in most cases) on the utilization of a matrix that absorbs ultraviolet (UV) light. Although lasers with other emission characteristics (e.g. in the infrared (IR) range) are also available today, the focus is still on UV lasers because they are nearly exclusively available on commercial mass spectrometers. The use of an appropriate matrix was independently introduced in 1988 by Hillenkamp and Karas[15] and Tanaka et al.[12] The technique has become an established tool in biochemical analysis, and the number of publications on the principles and applications of MALDI for biological problems is constantly growing (Figure 1).

There has been a tremendous increase in the number of publications dealing with this topic and it is nearly impossible to open a recent issue of a journal such as *Analytical Chemistry* or *Analytical Biochemistry* without finding at least one paper on MALDI/TOF MS. It is also evident from Figure 1 that there are less papers dealing

Table 1 Overview of the most important ionization techniques used in modern mass spectrometry

Method	General	Advantages	Drawbacks
Gas-phase ionization			
EI	Sample is ionized by EI. Most information is derived from characteristic fragmentation patterns. Mass limit is about 1000 Da	Applicable to nearly all volatile compounds. Can be easily coupled to separation techniques (e.g. GC/MS). High reproducibility	Compound must be thermally volatile and stable. Molecular ions are very often not detectable or extremely weak
CI	A reagent gas (e.g. ammonia) is ionized by an electron beam. The gas ionizes subsequently the sample. Mass limit is ca. 1000 Da	Molecular ion often detectable. Fragmentation strongly reduced in comparison to EI	Mass spectra highly dependent on gas type, gas pressure, and sample. Sample must be thermally stable
Field desorption and ionization			
FD	Sample is evaporized by a strong electric field. Typical mass range about 3–5 kDa	Little fragmentation. Simple mass spectra	Sensitive to contamination. Relatively slow measurements.
FI	Sample is evaporated by electron tunneling. Mass limit ca. 1000 Da	Little fragmentation. Simple mass spectra	Sample must be thermally volatile
Particle bombardment			
FAB	Sample is dissolved in a liquid matrix and ionized by bombardment with fast atoms (often argon atoms). For molecules up to 6 kDa	Rapid and simple. Composition of sample is less important	Analyte must be soluble in the matrix. High fragmentation and high background. Difficult to apply for mixtures
SIMS	Same principle as for FAB, but ions are used instead of fast atoms	Same as for FAB, but with higher sensitivity for higher masses (up to 13 kDa)	Fragmentation still more expressed than with FAB
Atmospheric pressure ionization (spray methods)			
ESI	Sample is sprayed across a high potential difference. Heat and gas flow are used to desolvate the ions. Maximum mass in the MDa range	Very easy to combine with e.g. chromatography. Very low background. Works best for high polar compounds	Very sensitive to contaminants. Multiple-charged species are formed. Apolar compounds difficult to analyze
Laser desorption			
MALDI	Ionization by laser irradiation of an additional matrix compound. Maximum mass ca. 1000 kDa	Rapid and accurate mass determination. Tolerates moderate quantities of impurities	Requires a mass analyzer, which is compatible with pulsed ionization techniques. Low reproducibility

GC/MS, gas chromatography/mass spectrometry.

with MALDI (white bars) than with ESI (black bars). The reader should note that this is not due to the lower importance of MALDI but due to the fact that ESI is also applicable to very small molecules as no matrix is used. Such molecules are difficult to analyze by MALDI only because of the significant contribution of matrix peaks in this mass region. This topic has been recently reviewed, for instance, in the excellent book by Hillenkamp and Peter-Katalinić.[26]

The most important observation for the development of MALDI was the minimal degree of fragmentation (in comparison with other MS techniques like LD) of the analyte achieved by using a suitable matrix compound. The matrix has two important tasks: to absorb the laser energy and to separate the analyte molecules from each other to avoid cluster formation. Therefore, the matrix and the sample are mixed in an appropriate solvent with an approximately 1000–10 000-fold molar excess of the matrix. The main requirements of a ''good'' matrix are its absorption properties at the laser wavelength used, the low extent of fragment ion formation, and good mixing properties with the analyte to give homogeneous crystallization.[27] Finally, the yield of matrix peaks should be very moderate, particularly if the analysis of small molecules is planned.[26] The sample–matrix mixture is subsequently placed onto a special sample probe tip (because it is irradiated by the laser, it is often called the *target*), which, for most instruments, allows the investigation of a number of samples. The required amount of sample is normally in the

Figure 1 Number of scientific papers containing in their abstract the terms ''MALDI'' or ''matrix-assisted'' (white bars) or ''ESI'' or ''electrospray'' (black bars) and the respective year of their publication. Data were taken from the ''Web of Science'' database.

picomol range. In Figure 2, a typical MALDI sample plate (PerSeptive, Framingham, MA; Voyager Technology) is shown alongside a standard 20-μL Eppendorf pipette tip for comparison.

As MALDI is regarded as a ''high-throughput'' method, larger ''targets'' resembling 384-well microtiter plates are nowadays available from many companies. Already a 0.5–2 μL of analyte–matrix mixture is sufficient to fill a well of the sample plate. The solvent is subsequently removed by air drying (or more rapidly by heating or drying under a slight vacuum) and cocrystallized analyte molecules dispersed within matrix molecules are obtained. Although this is still the most common sample preparation method, it is evident that cocrystals between matrix and analyte are never completely homogeneous. Therefore, the achievable signal intensity depends on the position where the sample is hit by the laser beam (''sweet spot phenomenon''). As this problem does not apply for liquids, the utilization of liquid matrices has been proposed.[28] However, the use of liquid matrices is still associated with rather low mass resolution, high background signals, potential instrument contamination, and poor ionization efficiency and has, therefore, not yet replaced the established matrix compounds.[26]

Figure 2 Typical sample plate (Voyager) for MALDI/TOF analysis comprising a 10 × 10 matrix of 1-μL wells etched into the stainless steel with gold cover. The dimensions of the plate are 57 × 57 mm and the individual wells are 2.54 mm in diameter.

A method called *surface-assisted laser desorption/ionization* (*SALDI*) that applies two-phase matrices was also recently introduced.[29] In addition to glycerol, a few liquid matrices, for instance, 3-nitrobenzyl alcohol, nitrophenyl octyl ether, and thioglycerol were already successfully used and detection sensitivities comparable to that by conventional crystalline matrices could be obtained. Finally, there are also protocols that use ''matrix-free'' approaches. This does not absolutely mean that there is no matrix at all, but there is no common organic, UV-absorbing molecule. The introduction of matrix-free desorption/ionization on electrochemically etched silicon surfaces (''DIOS'') has allowed the analysis of analytes with masses as low as 100 Da[30]; it is also known that silylation of the used porous silicon results in much-improved desorption/ionization on electrochemically etched silicon surfaces mass spectrometry (DIOS-MS) performance.[31] It is expected that further improvements of the understanding of the MALDI-ionization process (that is not yet clear at all) will also significantly increase the knowledge on more useful attempts of sample preparation.[32]

A description of the processes occurring at the sample in the mass spectrometer is given in Figure 3.

Figure 3 Schematic representation of events occurring in a conventional MALDI/TOF mass spectrometer. The analyte–matrix mixture is evaporated and ionized by laser irradiation. These ions are accelerated in an electric field and then allowed to drift in a field-free pathway. Over this distance, a separation between low-mass and high-mass ions occurs. The ''time-of-flight'' (t) depends on the flight path (L), the mass of the ion (m), its energy ($e\,U$), and the number of charges (z). (Figure was published in ref. 25, © Elsevier 2004.)

When the pulsed laser beam (we focus exclusively on N_2 lasers emitting at 337 nm) hits the probe, the laser energy is transferred to the UV-absorbing matrix, which is partially vaporized and carries intact analyte molecules into the vapor phase. In this expanding gas cloud, all ions ablated from the sample plate have nearly the same velocity of about 500 m s^{-1} and a half-width distribution of approximately 100 m s^{-1} (strongly dependent on the used matrix).[16] During the expansion of this gas cloud, protons and ions like Na^+ are exchanged between the analyte (often a protein, but lipids, many carbohydrates, deoxy ribonucleic acid (DNA), and artificial polymers can be analyzed in the same way) and the matrix molecules, leading to the formation of positively and negatively charged analyte molecules. Unfortunately, despite its importance for MALDI, the process of ion formation is only poorly understood so far, and further physical and chemical investigations are absolutely required.[11,33] However, an important difference between MALDI and the classic ionization techniques is that MALDI provides pulsed ion generation and not continuous ion formation. Requirements for the properties of the laser are stringent: to avoid thermal decomposition of the thermally labile molecules, the energy must be transferred within a very short time. Typical laser pulse widths are in the range 1–100 ns.[16]

Once formed, the ions are accelerated in a strong electric field, with typical accelerating voltages of approximately 20 kV. After passing a charged grid, the molecules drift freely over a field-free space, which is, for most MALDI/TOF spectrometers, in the range of 0.50–3 m. The length of this field-free TOF pathway influences the achievable mass resolution: ions of low mass arrive at the detector faster than do those of higher mass; consequently, ions of different masses can be separated. An appropriate recorder at the end of the flight tube produces a signal upon the impact of each ion group.[16] The TOF spectrum is a simple recording of the detector signal as a function of time. The relationship of time (t) with the square root of the mass-to-charge ratio $(m/z)^{1/2}$ is used to calculate the ion mass from the measured TOF, from which a conventional mass spectrum (intensity over the m/z ratio) is obtained. It must be emphasized that the ionization process does not only form positively charged ions.[11] Some molecules, especially acidic molecules carrying negatively charged groups, are more easily detected as negative ions than as positive ions. Switching from the detection of positive ions to the observation of negative ions is simply performed by inverting the polarity of the accelerating field.

Although a comprehensive theoretical treatment is outside the scope of this review, a few comments on the parameters influencing the mass resolution of MALDI/TOF mass spectrometers are necessary. Mass resolution ($m/\Delta m$) is a measure of a spectrometer's capability to produce separate signals from ions of similar mass. From the equation given in Figure 3, it is evident that the length of the TOF path (L) influences the mass resolution since the separation of the individual ions occurs over this distance. Therefore, resolution can be enhanced using longer flight tubes. However, to construct the small spectrometers with relatively short flight tubes that are preferred, a certain trick is used: ions are reflected at the end of the flight path by a so-called electrostatic mirror and reach the ''reflector detector'' at the opposite end.[16] A schematic comparison between the linear mode and the reflector mode is given in Figure 4.

Figure 4 Comparison between different configurations of MALDI/TOF mass spectrometers. The classical ''linear'' mode and the ''reflector mode'' of detection are shown.

Most modern mass spectrometers can be operated in both ways. Unfortunately, the gain of mass resolution in the reflector mode is accompanied by a loss of sensitivity since the total number of ions is spread over a wider range. Mass resolution obtained with common MALDI/TOF spectrometers is relatively poor in comparison with other MS methods, since ions exhibit a broad kinetic energy distribution that is largely a result of the initial velocity imparted to the ions during the desorption/ionization process. This leads to considerably broadened peaks in the mass spectrum. To minimize the influence of the initial velocity of the ions, modern MALDI/TOF spectrometers can be run in a special ''delayed extraction'' (DE) mode, where the velocity distribution of formed ions is minimized and, therefore, the mass resolution is enhanced. In short, a gradient field, not a constant electric field, is used for the acceleration of the ions. This field is high close to the ion source and decreases with the distance. Accordingly, the faster ions experience a weaker field, whereas the slower ions experience a stronger field. If the parameters are carefully adjusted, all ions with the same m/z value arrive at the detector at the same time and peak broadening effects can be avoided. This technique is also termed *time-lag energy focusing*.[34] Further information on this technique, which is now available on many mass spectrometers, can be found in some further reports.[16,34] The spectra of compounds with a relatively low molecular weight (up to 4 kDa) that are shown below were recorded with DE.

Of course, the determination of the molecular weight alone does not provide structural information and tandem mass spectrometry (MS/MS) is often required. Tandem mass spectrometry is the process of selecting an ion, causing it to fragment and obtaining a mass spectrum of the resulting fragment ions. Although MALDI devices with real MS/MS are nowadays commercially available, they are seldom used, as they are expensive. However, if MALDI-TOF devices with a reflectron are available, it is possible to record ''post source decay'' (PSD) spectra that may also be helpful to obtain some structural information on the compound of interest: A given parent ion penetrates to the back of the reflectron and may be easily focused onto the detector. Fragment ions of the parent ion do not penetrate as deeply and consequently, are not as well focused. This problem can be overcome by acquiring several spectra (known as *segments*) at reduced reflectron voltages. The different mass regions are then stitched together to form a single ''PSD'' spectrum representing principally an MS/MS spectrum. This ''PSD'' must be clearly differentiated from ''in source decay'' that occurs directly in the ion source and primarily contributes massively to the ''chemical spectral noise''.

TOF/TOF instruments may be additionally combined with ''collision-induced dissociation'' (CID): an inert gas (Ar or He at a certain pressure is commonly used) is introduced into a special collision cell between both TOF analyzers. The parent ion of interest is selected and transmitted into the collision cell, where collisions between the gas molecules and the parent ions will occur. By this energy transfer, fragmentations of the parent ions occur, leading to the generation of charged and neutral fragments that may help structural elucidation.

Further details on fragmentation processes are available in the excellent book by Hillenkamp and Peter-Katalinić.[35]

1.2 Coupling Matrix-assisted Laser Desorption/Ionization with Other Mass Analyzers

As already mentioned above, MALDI is characterized by a pulsed, but not a continuous generation of ions. Therefore, historically MALDI has always been coupled to TOF analyzers, since these analyzers are most suitable for monitoring the pulsed events taking place in the ion source. However, at least for more sophisticated analytical problems, there has been a strong need to combine the unique properties of the MALDI-ionization technique to other mass analyzers. Some of these reasons are as follows:

- to obtain more accurate mass determinations than achievable by simple TOF analysis;
- to improve the isolation selectivity of parent ions in MS/MS;
- to have access to multistage fragmentation (MS^n).

There were two important problems that had to be solved. The first problem was the pulsed ion generation of the MALDI source, but this problem could be overcome with the invention of more rapid pulsing lasers. Lasers pulsing in the range of kilohertz (thousand times per second) provide nearly a continuous ion stream. The second problem was to avoid the decay of the generated ions prior to their analysis. This problem was solved

by ''cooling'' the ions of interest by collisional damping before their extraction by increasing the gas pressure in the ion source. These attempts are known as *intermediate pressure* or *atmospheric pressure* MALDI.[36]

The comparison between vacuum and (in particular) atmospheric pressure MALDI extends further the knowledge of fragment ion generation and may help identify the structure of unknown compounds. However, peak intensities are generally higher in the vacuum MALDI spectra. A comprehensive comparison of vacuum MALDI and ''atmospheric pressure'' MALDI regarding ''proteomics'' was recently provided.[36]

Although a comprehensive discussion of the different mass analyzers used in modern MS is clearly outside the scope of this article, a short summary is provided in Table 2. A more comprehensive treatment of this important topic is available in the recent book by Hillenkamp and Peter-Katalinić.[35] Different ionization methods as well as vacuum and atmospheric pressure detection were recently compared.[37]

1.3 Biological Molecules and Related Chemistry

In this article, the more general term ''structural biology'' is used to describe the molecules responsible for the highly ordered structures of living beings, e.g. the membranes of cells and connective tissues.[38] Interestingly, a relatively small number of similar, ubiquitous molecules achieve the structural integrity seen in living organisms. This article gives a short overview of such basic molecules, including lipids (particularly phospholipids (PLs)), proteins, and carbohydrates (especially polysaccharides).

1.3.1 Lipids

All higher organisms comprise a large number of cells that are highly differentiated into specific cell

Table 2 Overview of the most important mass analyzers used in mass spectrometry

Instrument	m/z Range	Mass resolution	Mass accuracy	Sensitivity	Remarks
Quadrupole (Q)	2–4000	1×10^3	0.1 Da[a]	0.5–1 pmol	Often combined with IT. One disadvantage is that only one ion is measured at a time. Thus, much available information is discarded. This can be overcome by the so-called o-tof, where the fragment ions are accelerated orthogonally and all of them are detected by the TOF analyzer
MALDI/TOF (Reflectron)	Unlimited	2×10^4	20 ppm	1–10 fmol (peptide) 1–5 pmol protein	The TOF analyzer is still the most useful analyzer for MALDI because it is most suitable for pulsed ion generation. The introduction of very rapid pulsing lasers (1000 Hz), however, made coupling with other detectors possible. Nowadays, TOF/TOF devices are also available (large devices and very expensive!)
IT	20–6000	1×10^3	0.1 Da	10–20 fmol	Often combined with Quadrupole Ion Trap (QIT) and often used as inexpensive mass analyzers. Ions can be fragmented by collision with e.g. He gas and the daughter ions analyzed within the trap. Selected daughter ions can undergo further fragmentation, thus allowing MS^n. Linear trap and orbitrap were developed to overcome problems with mass accuracy of standard IT devices
FTICR	>15 000	1×10^6	~0.1 ppm	20 attomol	May be regarded as combination of IT and a superconducting magnet. The strength of the magnetic field is very important and influences MS quality. Therefore a tendency to higher field is evident. Highest recorded mass resolution of all mass spectrometers. However, devices are large and very expensive. Not a high-throuhput method

IT, ion trap; FTICR, Fourier transform ion cyclotron resonance.
[a] Depends on the mass window being used.

types to fulfill individual tasks. However, all cells have certain common structures: cells are separated from the extracellular space by a membrane consisting of a highly ordered lipid bilayer. This cell membrane is essential for the transport of molecules in and out of the cell. The membrane is composed of a small number of different lipid classes **(1–3)**, mainly phosphatidylcholine (**(2)**; PC), phosphatidylserine (**(1)**; PS), and phosphatidylethanolamine (**(3)**; PE). All these lipids possess, besides their relatively hydrophilic polar headgroup, two lipophilic fatty acyl residues. It is very common that saturated and unsaturated acyl residues are located in *sn*-1 and in *sn*-2 positions, respectively (stereospecific numbering).[25]

(1)

(2)

(3)

This marked amphiphilicity enables such lipids to form the characteristic bilayer in an aqueous environment. The formation of this bilayer is a unique feature of PLs. One main problem in the analysis of lipids of natural origin is that they consist of a variety of different fatty acyl residues, derived from the saturated palmitic acid (16:0) up to the highly unsaturated docosahexaenoic acid (22:6).[38] The acronym (x:y) is the usual nomenclature for fatty acids and lipids. Here, "x" represents the number of carbon atoms and "y" the number of double bonds in the fatty acyl residues of the lipid. Sometimes, if no further distinction is required, both residues of a given lipid are combined in this nomenclature. For instance, "36:2" may indicate the presence of two oleoyl (18:1) residues or one stearoyl (18:0) and one linoleoyl (18:2) acyl residue.[39]

Although investigations of lipids have been neglected over a long period of time, there is growing evidence that lipids like phosphatidylinositol phosphates or phosphatidic acid (PA) and diacylglycerols (DAGs) (**(4–6)**, respectively) play an important role in signal transduction processes, where they serve as messenger molecules.[40] The increasing interest in lipids and their physiological relevance is also reflected by the introduction of the term "lipidomics".[41,42]

(4)

(5)

(6)

1.3.2 Proteins

Proteins play an important functional role in all living organisms, especially as biocatalysts and receptors. Additionally, proteins are the macromolecules that allowed the evolution of higher animals, since without the introduction of an active transport mechanism for oxygen (hemoglobin and myoglobin), the size of an organism would be strictly limited by diffusion processes.[38] Finally, proteins form the largest part of the dry weight of the human body, since proteins are also important components of muscles and of connective tissues. In tissues such as skin, cartilage, bones, and tendons, collagen comprises a larger moiety, providing the mechanical stability of such tissues.[43,44] The analysis of proteins and peptides is one of the main applications of MALDI/TOF MS and there are some excellent reviews on this topic.[16,17,45,46] Consequently, protein analysis will be treated relatively lightly here and only some important examples will be given. The interested reader is also referred to some recent reviews dealing with mass spectrometric investigations of the structural biology of proteins.[35,47]

1.3.3 Carbohydrates

Simple carbohydrates like glucose, fructose, or saccharose are important ''fuels'' for living organisms.[43] The polysaccharides mainly fill important structural roles. For example, they constitute the largest part of the exoskeleton of insects and marine organisms in the form of chitin and its deacetylated form, chitosan **(7)**, a positively charged polysaccharide. It is thought that chitosan is the most abundant polysaccharide on earth.[43]

(7)

A similar, but negatively charged, polysaccharide in the flora is alginate **(8)**, which is a widespread component of plants, e.g. brown algae.[43] Polysaccharides like dextran **(9)** or starch are the storage form of carbohydrates in many living organisms; in addition, naturally occurring carbohydrates can be used therapeutically, for example, heparin **(10)** as an anticoagulant. Although the contribution of polysaccharides such as chondroitin sulfate (CS) and hyaluronic acid (HA) ((**11**) and (**12**), respectively) in the connective tissues is relatively low, many diseases are thought to be linked with damage to carbohydrates in the connective tissue, e.g. rheumatic diseases with cartilage degradation.[48] Since the number of patients suffering from rheumatic diseases is constantly growing, such processes are of great socioeconomic significance, and the analysis of relevant polysaccharides by MALDI/TOF will also be discussed.[49]

2 ADVANTAGES OF THE ANALYSIS OF BIOMOLECULES

MALDI/TOF MS offers a nearly unique possibility to analyze very small quantities of biological (detection limits down to the zeptomole (10^{-21} mole) range have already been reported),[50] highly polar, and less-volatile macromolecules, such as proteins and carbohydrates. In comparison with other MS techniques, the extent of fragmentation reactions is extremely low and the molecular ions (i.e. ''quasimolecular'' ions) are detectable in most cases. This is an advantage in the analysis of crude mixtures such as extracts of biological tissues or body fluids. However, one should always be aware that individual molecules in mixtures may be detected with different sensitivities.[35] A further advantage of MALDI/TOF MS is that mainly singly charged molecular ions are formed.[16] This leads to mass spectra that are easy to interpret, since each individual molecule results in a single peak. It makes MALDI/TOF a suitable tool for the analysis of mixtures without previous separation of the individual components, although the suppression of less sensitively detectable compounds by more sensitively detectable compounds should be always considered. This will be outlined below in more detail.

Finally, MALDI/TOF mass spectra can be easily and quickly recorded and no extensive sample clean-up is needed.[51] The commonly used buffers for sample preparation do not markedly influence the quality of the mass spectra. In this sense, MALDI is obviously superior to similar MS methods such as ESI, which is strongly affected by such impurities.[10] Nevertheless, one should always bear in mind that all salts (in particular, polyvalent ions as SO_4^{2-}, Ca^{2+}, PO_4^{3-}, etc.), buffers, and detergents deteriorate the achievable signal intensities and line widths.[52] The solvent of choice is, therefore, distilled water.

3 INTERPRETATION OF A GIVEN MASS SPECTRUM

Although MALDI/TOF mass spectra are generally easy to interpret, a few remarks on the characteristic features of MALDI/TOF spectra are useful. All modern MALDI/TOF mass spectrometers directly calculate the mass-to-charge ratio of the unknown compound from the TOF, which is the actually measured quantity. The number of counts (i.e. the number of ions reaching the detector) is normally plotted against the mass-to-charge ratio. In most standard measurements, the number of counts must not be overestimated since this value is influenced by many parameters, in particular, the applied laser strength.[53] The number of counts is also difficult to reproduce because of the inhomogeneity of the analyte–matrix mixture[54] and, therefore, the inhomogeneity of crystal formation.

The accessible mass resolution of MALDI/TOF spectra depends strongly on the individual compounds: high-molecular-weight compounds do not yield isotopically resolved peaks, but these can be obtained if substances with a lower molecular weight (up to about 4 kDa) are investigated. As a typical example of a compound yielding isotopically resolved peaks, the expanded region of a spectrum of an aqueous solution of adenosine triphosphate (ATP) recorded with 2,5-dihydroxybenzoic acid (DHB) as matrix is shown (Figure 5).

Since ATP possesses negatively charged phosphate groups, positive (Figure 5a) as well as negative ions (Figure 5b) are produced upon laser irradiation. MALDI/TOF spectra often represent the content of ions within the sample, leading to characteristic adduct ion signals. As one can clearly see from the mass difference of 22 Da, both spectra in Figure 5 were recorded in the presence of large quantities of Na^+, which compete with protons for the binding site at the phosphate group ($M - H^+ + Na^+$). The fact that ATP gives more than a single (isotopically resolved) peak is very typical for a biological environment. According to its monoisotopic mass of 551 Da for the disodium salt, the corresponding protonated ion ($M + H^+$; $m/z = 552$) is easily found in the positive ion spectrum. However, this peak is accompanied by four additional peaks arising from an exchange of the protons with Na^+ ($m/z = 574$ and 596) or the two Na^+ with protons ($m/z = 508$ and 530). The presence of five peaks is, therefore, typical for compounds with four negative charges. The negative ion mode provides a simpler spectrum, yielding only three intense peaks that are shifted compared with that seen in the positive ion mode to lower masses (less than 2 Da) as a consequence of the loss of two protons (e.g. $m/z = 528$ instead of 530).

Of course, the sample may be purified prior to MALDI/TOF mass spectrometric characterization and the Na^+ concentration may be decreased. However, according to our experience, it is nearly impossible to remove Na^+ ions completely from biological samples. In cases of mixtures, where, for instance, H^+ and Na^+ adducts overlap and obscure an important mass region of the spectrum, the addition of an excess of CsCl is a convenient method of shifting masses of interest.[55]

Figure 5 Positive (a) and negative (b) ion spectra of a 0.1 mg mL^{-1} sample of ATP in pure water. Spectra were recorded with a 10 mg mL^{-1} aqueous DHB matrix in the reflector mode of the mass spectrometer.

4 PREPARING SAMPLE–MATRIX MIXTURES

In most instrumental analytical procedures, the quality of the resulting spectra is influenced by a variety of different parameters, which have to be set appropriately; however, in MALDI/TOF methodology there are only two parameters that have a major impact on the quality of the mass spectra. These are the homogeneity of the sample–matrix cocrystals and the applied laser intensity; these determine the extent of fragmentation and, therefore, the quality of the spectra.[56]

Consequently, it is wise not to underestimate the preparation of the analyte–matrix layer because this is the most important step in MALDI/TOF analysis, although this procedure sounds simple.

4.1 How to Choose an Appropriate Matrix

The first MALDI/TOF mass spectra of proteins were successfully recorded by Karas and Hillenkamp[15] using nicotinic acid as a matrix. However, this substance is no longer considered to possess ideal properties for MALDI/TOF analysis since it exhibits a strong tendency to fragment. A large number of useful matrices are now available for different applications[11,27,57] and the MALDI user must carefully choose the matrix that is appropriately adapted for his requirements. Lists of suitable matrix compounds are, for instance, available in the MALDI book by Hillenkamp and Peter-Katalinić.[35]

Since all the compounds suitable as matrices have both advantages and disadvantages, in this article only a small number of common matrix compounds that are currently used in our laboratory and their most important analytical applications are discussed (Table 3).

Since we use a pulsed nitrogen laser emitting at 337 nm, all matrix compounds must show strong absorptions at this wavelength; however, there are also a number of matrix compounds that are suitable for IR lasers (e.g. glycerol or the widely used tris(hydroxymethyl)aminomethane (TRIS) buffer).[27]

Finding the best matrix is a rather empiric process and only a few guidelines can be given. No single matrix compound is suitable for all analytes.[27] Generally, DHB (**(13)**, gentisic acid) is useful for small, particularly highly polar, molecules (e.g. for carbohydrates), since it has only a low tendency to fragmentation and represents a very ''fast'' matrix, i.e. the arising ions possess high initial velocity.[11] DHB dissolved in a solvent such as methanol is also suitable for the quantitative analysis of lipids.[56] Although different isomers of dihydroxybenzoic acid are known, only the 2,5-isomer is suitable as MALDI matrix.[58]

An additional advantage of DHB is that it can be used in the positive as well as the negative ion mode. In the field of protein and peptide research, however, DHB is used less often. In these cases, sinapinic acid (**(14)**; 3,5-dimethoxy-4-hydroxycinnamic acid)[59] or α-cyanohydroxycinnamic acid **(15)** for smaller proteins[60] should be used in the positive ion mode and 2,4,6-trihydroxyacetophenone **(16)** when the negative ion mode is of special interest.[61] Mixtures of different matrices are also sometimes recommended.[62]

One should note that nowadays there are also ''matrix-free'' approaches that enable the evaluation of even small masses without interfering matrix signals. This topic has been very recently reviewed.[63] A quite similar approach is the use of graphite or even pencil lead as ''matrix''.[64]

4.2 Finding the Appropriate Solvent–Analyte Mixture

The importance of the homogeneity of the analyte–matrix crystals in determining the quality of the MALDI spectra is a fact that is often neglected. Since the analyte–matrix cocrystallization from a solution containing both compounds depends on the solvent used, the choice of the solvent is most important. A ''good'' solvent in the context of MALDI/TOF MS is a solvent in which both analyte and matrix are readily soluble. It is also advisable to use highly volatile solvents, whereas the application of solvents with a high boiling point (e.g. dimethyl sulfoxide, DMSO) is not recommended. Since the matrix must isolate the analyte molecules from each other (to prevent aggregation) in addition to allowing ion formation, the sample–matrix mixture should homogeneously crystallize when the solvent evaporates.[16] In a poor solvent, one component (the matrix or the analyte) would crystallize prior to the other one, resulting in separation of analyte-rich and matrix-rich compartments. In many cases, mixtures of different solvents (e.g. trifluoroacetic acid (TFA), acetonitrile (ACN), and water)[53] have to be used, since the matrix is more readily soluble in less-polar

Table 3 Guidelines for the preparation of suitable analyte-sample mixtures for the most important classes of biological molecules

Compound	Matrix/solvent	Conditions	Remarks
Peptides + proteins	Sinapinic acid (10 mg mL^{-1}) in a mixture of TFA, water, and ACN (1:4:5, v:v:v, or similar volume ratios). Sample preferably in pure water. α-Cyano-hydroxy-cinnamic acid can also be used	Cover 1-μ L sample solution with about 1.5-μ l matrix solution. No phosphate should be used for the sample. Preferably use buffers like HEPES or TMEDA	Allow the sample–analyte mixture to crystallize slowly at ambient temperature (the application of a slight vacuum may help improve the homogeneity of crystallization)
Carbohydrates	Use a saturated DHB solution in water (about 10 mg mL^{-1}) for high-molecular-weight carbohydrates or water–methanol (ethanol) mixtures for low-molecular-weight compounds. The use of arabinose osazone is also convenient in a number of cases	Highly dependent upon the chemical structure of the carbohydrate under investigation (the analysis of neutral carbohydrates is much more easier than that of strongly acidic ones):	Since carbohydrates and matrix differ considerably in their solubilities, the mixture tends to separate. Crystallization is normally very poor. The recrystallization of the mixture from a small quantity of ethanol may help improve the homogeneity of crystallization (difficult to perform!)
	2,4,6-Trihydroxyacetophe-none is a useful matrix for the negative ion mode	1. mix sample with matrix directly on the sample plate 2. premix matrix and sample in a small Eppendorf tube The sample/analyte mixture should be dried under a warm stream of air (hair-dryer)	
Lipids	DHB (0.5 M; 77.1 mg mL^{-1}) in methanol (ethyl acetate may also be used, if less-polar lipids have to be analyzed)	Place ca. 1 μ L of lipid sample on the sample plate, followed by an addition of 1 μ L of matrix solution (caution: organic solvents will readily "spride" over the metal surface). Under an air stream, very homogeneous analyte–matrix crystals are formed	Lipid and matrix compounds are readily soluble in the same (organic) solvent. This enhances the homogeneity of crystallization considerably. This makes lipids one of the most easy to analyze substance class
	Sample should be dissolved in chloroform or in $CHCl_3$–CH_3OH mixtures		

ACN, acetonitrile; HEPES, *N*-(2-hydroxyethyl)piperazine-*N*′-ethanesulfonic acid; TFA, trifluoroacetic acid; TMEDA, *N*,*N*,*N*′,*N*′-tetramethylethylenediamine; DHB, 2,5-dihydroxybenzoic acid.

solvents such as ethanol or ACN, whereas the analyte often requires highly polar solvents such as water (often also in the presence of a certain amount of acid). The higher the difference between the polarity of the analyte and that of the matrix, the more difficult it is to obtain a homogeneous sample–matrix mixture. Table 3 lists some appropriate solvents or solvent mixtures for different substance classes.

Since spectra are mainly recorded in the positive ion mode, a cationizing species is often added along with the matrix to increase the concentration of ionized species.[16] Although biological samples nearly always contain cations such as alkali metals (Na^+ and K^+), the addition (of low amounts) of TFA has been found to be useful for biological samples. Finally, mass spectra of biological samples always reflect the natural ratio between Na^+ and K^+ (e.g. in the used buffer). That means that H^+, Na^+, and K^+ adducts are often simultaneously detectable in biological samples. However, an equilibrium exists between these different forms and that can be strongly

influenced by the addition of ions that occur naturally only at negligible levels (e.g. Cs^+).[55]

4.3 Mixing the Matrix with the Analyte

There are two different methods for preparing a sample spot for MALDI. The first method is to mix sample with matrix and to transfer this mixture subsequently to the sample plate. Although frequently recommended, this method should only be used if pure solvents, not solvent mixtures, are used. With mixtures of solvents, one less-soluble component (usually the analyte) precipitates and is not easily detected. Consequently, direct mixing of analyte and matrix on the sample plate is often advisable.[65] About 1 μL of analyte is transferred to the MALDI target, followed by 1 μL of matrix solution, which should be prepared shortly before use. Matrix solutions should never be stored over several hours since they change with time.

It is strongly recommended to add analyte before matrix; if the matrix is added before the analyte it may start drying before it mixes with the analyte, and this may result in uneven sample–matrix crystals. Touching the sample plate with the fingers or with the pipette tip must also be avoided since this may cause uneven crystallization. Finally, the surface of the sample plate is rather sensitive to mechanical or chemical treatments. During cleaning of the sample plate, actions such as brushing that could damage the surface of the plate should be avoided, as damage can also lead to uneven crystallization. The sample plate should not be put in solutions containing high concentrations of detergents or strongly alkaline or acidic conditions for more than a few minutes.

Recently, the so-called add-on technique has been introduced, which confers enhanced sensitivity.[65,66] Here, only the matrix is primarily transferred to the sample plate. After crystallization of the matrix, the sample is added on top of the matrix crystal and gives a large signal when such a ''hot spot'' is directly hit by the laser and no signal when the laser does not. This technique has been successfully used in the field of lipid analysis.[66] Unfortunately, the fluctuations from shot to shot are high.[56]

As mentioned above, MALDI tolerates considerable amounts of buffer compounds, detergents, and salts. However, some common anions like sulfate or phosphate as well as high amounts of Na^+ strongly decrease molecular ion formation, whereas the influence of organic, nonionic buffers such as *N*-(2-hydroxyethyl)piperazine-*N*′-ethane sulfonic acid (HEPES) is only weak. The influence of different commonly used buffers and salts has recently been thoroughly investigated.[67]

If the sample cannot be desalted prior to the measurement (e.g. by ion-exchange chromatography), the analyte–matrix mixture can be directly ''washed'' on the sample plate. This requires that the impurities are more readily soluble than the analyte itself. In this case, a small amount of water is added to the dried analyte–matrix mixture and is removed after about 10 s by sucking it off with a pipette. This process can be repeated several times. Another important method for the purification of contaminated samples prior to MALDI analysis is drop dialysis.[68] Here, a few microliters of a protein sample are deposited on a membrane floating on top of pure water. This drop is retrieved after about 30 min with a micropipette. However, desalting the sample prior to its application to the sample plate is preferred. Very recently, specially designed pipette tips containing a layer of an ion-exchange resin, which allows the direct desalting of the sample, became commercially available (ZipTip™, Millipore). The protein solution of interest is prepared in diluted TFA. Under these conditions, proteins are positively charged and bind to the negatively charged resin, whereas all further neutral molecules and strong electrolytes as salts are not bound. After one or two washing steps of the resin, an alkaline solution is used for re-elution of the protein from the resin. Using this method, proteins can be easily purified and concentrated.

Highly diluted samples cannot be concentrated easily by evaporating the solvent, as potential impurities would be concentrated too. For that purpose, special ''anchor'' sample plates were developed and are commercially available now. These special targets have small hydrophilic islands, typically of 100–500-μm diameter, placed on a hydrophobic surface.[69] The purpose of the hydrophobic surface is the prevention of the spreading of the sample solution over a large area: during crystallization, the applied solution contracts onto the hydrophilic islands, thereby concentrating the matrix and the analyte into a defined volume. If impurities are significantly less polar than the analyte of interest, a separation between both may be also achieved by this simple procedure.

5 RECORDING MASS SPECTRA

On a modern MALDI/TOF mass spectrometer, the acquisition of mass spectra is very simple because only a few parameters have a major impact on the quality of the spectra. As a guideline for recording the very first MALDI/TOF spectra, it is strongly recommended to use the acquisition files provided by the manufacturer and a sample of known composition. The first aim should be to obtain a spectrum with a sufficient signal-to-noise ratio (S/N) and an adequate mass resolution as a starting point for further optimization of the parameter set.

5.1 Important Instrumental Parameters

All adjustable parameters are highly dependent upon the type of spectrometer used; therefore only some general guidelines can be given. Since modern mass spectrometers often provide the possibility of working in a number of different acquisition modes (positive/negative ion detection mode, continuous or DE and, finally, reflector or linear mode), the chemical composition and the molecular weight of the analyte are of special interest.

For molecules exceeding a molecular weight of about 4000 Da, the easiest way to implement the linear mode with continuous extraction should be used. This method provides the highest sensitivity and only a low amount of fragmentation[16] because the path of flight is short. However, the peaks are broader than in the DE mode because of the significant velocity distribution of ions that is least partially compensated using the DE mode. Since high-mass molecules yield broad peaks through strong adduct formation, mass resolution is not so important. For such analytes, the accelerating voltage should also be set to its maximum value (often 25 kV), providing the highest sensitivity. The so-called ''low mass gate'' is used to avoid the saturation of the detector with low-molecular-weight ions derived from matrix degradation. This gate prevents the activation of the detector until ions greater in mass than the selected value pass the detector. Setting the low mass gate too close to the peaks of interest should be avoided because under these circumstances peak shapes as well as the achievable mass accuracy may be negatively affected. If an expected peak at lower mass is missing or is poorly resolved, the same spectrum should be recorded without the low mass gate and the individual spectra compared. All other parameters that have to be set for the use of DE and the reflectron (both recommended for smaller molecules) are given in the manual of the spectrometer. It is outside the scope of this review to give a comprehensive overview on this topic.

5.2 Laser Power

Besides homogeneous analyte–matrix crystallization, the applied laser power is the second parameter that has a major impact on the quality of the mass spectra. It is strongly recommended to set this parameter as low as possible within the power levels required. Whereas higher laser power often confers an enhanced signal-to-noise (S/N) ratio, it also causes more fragmentation and a decreased mass resolution; using a lower laser power (only a small amount over the threshold level) improves the mass resolution, especially the quality of the baseline. Furthermore, increased laser power leads to enhanced intensities of metal and matrix adducts, confers enhanced formation of doubly and triply charged ions (at one half and one-third of the expected molecular mass) and, finally, leads to the formation of dimers (at the double molecular mass). The required laser power strongly depends on the substance class that is under investigation. For example, it has been shown that the minimum, or threshold, laser irradiance necessary to produce protein ions from a sample is about 10 mJ cm^{-2} for a 10-ns laser pulse width.[16] Near the threshold, ion production falls off with the fifth power of laser irradiance.[16] Generally, a laser intensity of about 10% over threshold is a suitable setting for most measurements.[70]

Whereas oligopeptides give a strong signal even at relatively low laser intensity, acidic carbohydrates require maximum laser intensity. Increased laser strength is also required when a large amount of ionic impurities are present. The applied laser intensity is the main reason why spectra obtained at different MALDI spectrometers are difficult to compare: most suppliers provide only a relative scale of the used laser intensity and, therefore, these settings are difficult to compare with those on another mass spectrometer.[58]

5.3 Standards of Mass Calibration

In MALDI/TOF MS, calibration adjusts the mass assignment for the acquired data. The software of most mass spectrometers includes a default calibration routine (only the matrix has to be specified) that provides an adequate mass accuracy (deviation approximately 0.1%) for many applications. However, if optimum mass accuracy is required, a calibration based on the observed TOF of a known mass of a special calibration standard should be performed. This standard must have a similar mass and should be of similar structure to the analyte.[71] For example, a lipid should serve as calibration standard when lipids are investigated.[56] The calibration standard may be measured individually (external calibration) or be included in the analyte (internal calibration). The basic equations used in the calibration process were described in more detail by Juhasz et al.[72] These authors determined the initial velocity of ions in specific matrices and introduced corresponding correction terms. This correction is particularly necessary if different delay times are used in the DE mode.[72]

For the first experiments to calibrate the mass spectrometer, the use of a known low-molecular-weight substance (e.g. an oligopeptide that gives highly resolved peaks) is strongly recommended. Using this substance, the effects of different settings on the quality of the calibration file should be tested. The use of the linear mode and the reflectron mode requires different calibration files and sometimes (particularly if larger targets are used) differences are also found depending on the sample position on the sample plate.

Mass accuracy is typically given in parts per million (ppm). For example, 50 ppm means that the real mass of an ion measured to 1000 Da has a predicted error margin of ±50 mDa. One should note that the mass accuracy is also determined by the number of data points that are sampled for each mass spectrum as the number of points determines the center of a peak as accurately as it can be determined.[73]

6 APPLICATION OF MASS SPECTROMETRY TO THE ANALYSIS OF BIOMOLECULES

The following short overview of the most important, biologically relevant substance classes describes experiments with isolated components, where possible spectra of biological samples, such as body fluids or cell suspensions, are described as examples of the applications as well as the limitations of MALDI/TOF analysis.

6.1 Small Molecules and Common Impurities of Biological Samples

Although not originally developed for such purposes, MALDI/TOF MS is also suitable for the detection of low-molecular-weight compounds with masses of a few kDa occurring typically in biological samples (e.g. carbohydrates). Such low-molecular-weight compounds (e.g. oligopeptides) were the first compounds where the possibilities of quantifying MALDI/TOF mass spectra were demonstrated.[74] Although low-molecular-weight compounds often interfere with the matrix, such compounds are usually easily detected because their molecular weight is known. Typical examples of such molecules are reduced nicotinamide adenine dinucleotide (NADH), ATP (Figure 5), different kinds of lipids and PLs, and carbohydrates like saccharose or glucose, all of which can be found in most cell and tissue extracts.

Because of its high sensitivity, MALDI also detects a number of impurities in biological samples.[75] A very common impurity, especially in commercially available biochemicals, is poly(ethylene glycol) (PEG). This polymer plays a major role as an additive in a number of biological processes,[76] such as the precipitation of proteins from solutions. Fortunately, PEG can be easily distinguished as it has a typical peak pattern, reflecting the molecular weight of the repeating unit and the distribution of the molecular weight.[34] PEG is mainly synthesized from ethylene glycol by polycondensation or from ethylene oxide by anionic ''living'' polymerization. The molecular weight of its repeating unit $-CH_2-CH_2-O-$ is 44 Da and this can be identified among the peaks of the spectrum.

In Figure 6, the influence of the acquisition parameters and the molecular mass of PEG is shown. The spectra in (a) and (b) were obtained with a PEG 1500 sample, whereas (c) used a PEG 6000 sample.

Spectra (b) and (c) were recorded in the linear mode, and (a) was recorded using a reflectron. It is evident that (a) exhibits improved mass resolution since the reflectron enhances the flight path and compensates for the differences in flight time of ions with equal mass-to-charge ratios but different initial velocity.

The linear mode spectrum is characterized by decreased mass resolution but higher sensitivity. There may be slight differences between the determined mass-to-charge ratios in the linear and the reflectron mode (cf. Figure 6a and b); consequently, different calibration files have to be used for the two modes.[16] Although the use of the reflector mode would be valuable for the analysis of synthetic polymers and, therefore, for industrial research, polymers with a higher degree of polymerization cannot be measured in this way. As shown in Figure 6 for spectra obtained in the same manner but with differing degrees of polymerization of PEG (b and c), the larger polymer (average 6 kDa) has a broad mass distribution that prevents identification of other individual molecular species. However, it has been shown that the application of more sophisticated techniques (such as DE conditions) still allows the acquisition of highly resolved mass spectra of polymers (e.g. PEG 20 000).[34] Again, the matrix used plays the most important role and great care is needed to select a suitable compound (DHB is good for many synthetic polymers).[75] Detergents based on ethylene glycol such as triton, Brij, Myrj, Tween, and Tagat are often used to solubilize membrane proteins. Their mass spectrometric characteristics were investigated very recently, and it could be clearly shown that all these detergents give very typical mass spectra, allowing the differentiation of the individual compounds.[77]

In addition to such high-molecular-weight impurities, most biological samples contain a large number of compounds (buffer salts, detergents, small carbohydrates like glucose, amino acids, etc.) that possess a molecular weight similar to the matrix. Although these compounds can be eliminated to some extent by the low mass gate, a large amount of such molecules may affect the quality of mass spectra by adduct formation and may considerably reduce ion formation.[66]

Finally, it must be kept in mind that most matrix compounds undergo a slow polymerization process, even in the solid state and especially in aqueous solution. For example, cinnamic acid derivatives yield upon aging (owing to the presence of the alkenic residue) intense peaks of polymeric products (between about 11 and 18 kDa). Therefore, it is advisable that all matrix solutions are always freshly prepared. Additionally, the starting

Figure 6 Comparison of the MALDI/TOF mass spectra of commercially available PEG 1500 (a,b) and PEG 6000 (c). Spectrum (a) was recorded with a reflectron and in the DE mode, whereas (b) and (c) were recorded in the linear mode. A 0.1 mg mL^{-1} PEG sample and a 10 mg mL^{-1} DHB solution in H_2O were used. Note the higher intensities but significantly enhanced line widths if the spectra are recorded under ''linear'' conditions.

material should be replaced after a fixed time by a new charge.

It should also be realized that UV-absorbing compounds can be characterized by MALDI/TOF even in the absence of an additional matrix.[78] Under these conditions, the compound under investigation serves simultaneously as matrix and as analyte. Here, the term *LD* spectrum instead of *MALDI* should be used. Unfortunately, this is only possible for compounds of molecular weights up to about 3 kDa. Beyond this size, the energy needed for resonant absorption is greater than the energy required for dissociation of the molecule.[16]

6.2 Proteins

One of the main applications of MALDI/TOF MS is the investigation of proteins, especially oligopeptides.[11,16–18] The main advantages of MALDI/TOF in this context are the simple experimental setup, a rapid procedure, and, finally, the high mass resolution (e.g. in comparison with electrophoresis). These advantages of MALDI/TOF have already led to the introduction of highly automated mass spectrometers for the analysis of unknown proteins.[59] Here, the protein of interest is subjected to different enzymatic digestions, and the digests (usually obtained by treatment with trypsin) are subsequently analyzed by MALDI/TOF (''peptide mapping''). The concept of peptide mass mapping for protein identification by combination of MS and protein sequence database searching was already proposed in 1993 by different research groups.[79] This peptide mass fingerprinting (PMF) approach of protein analysis is also referred to as the ''bottom-up'' approach. Since there are many papers[80] available on this subject, this is not outlined here in more detail. Detailed descriptions of

methodological approaches[81] as well as excellent reviews are also available.[82] Suppliers of mass spectrometers have also significantly contributed to the progress in this field, and nowadays, highly automated devices equipped with nano-LC systems coupled to Robot MALDI-spotters are commercially available.

The reader should note that the reliable analysis of peptide mixtures obtained by enzymatic digestion of a certain protein requires very high mass accuracy as inaccuracy increases the number of hits upon database searching significantly. Although very large databases are nowadays available, not all obtained peptides will be actually available. Therefore, ''de novo sequencing'' of such an unknown peptide by using the interpretation of peptide fragment patterns is often necessary. Finally, isobaric amino acids such as leucine or isoleucine are still difficult to differentiate by MS methods.

As one representative example of a MALDI/TOF mass spectrum of an intact protein, Figure 7 shows the positive ion mass spectrum of a commercially available serum albumin (molecular weight approximately 67 kDa).

This spectrum is relatively simple to interpret and consists only of three different peaks. Whereas the most intense peak at the highest mass-to-charge ratio represents the singly charged molecular ion, the remaining two peaks at about 33 and 22 kDa correspond to the doubly and triply charged molecular ions, which appear with decreasing intensity compared with the singly charged molecular ion. Such multiple-charged ions are found in most cases when proteins are investigated and are affected by the applied laser intensity only to a small extent. By comparison, the formation of protein dimers, which is clearly reflected by the formation of peaks at the double mass-to-charge ratio (for albumin at approximately 134 kDa, data not shown), is highly influenced by the applied laser intensity and can be minimized by using a lower intensity.[17] A high extent of dimer formation even at moderate laser intensity may also indicate that the protein concentration within the sample is too high and that the sample should be further diluted with the solvent or the matrix.

One further recent application of MALDI/TOF MS is the detection of covalently modified amino acids in larger proteins (''posttranslational modification''). More than 200 different posttranslational modifications are currently known, and they give rise to a characteristic mass increase of certain amino acid residues, and thereby, the peptides obtained after an enzymatic digestion of the protein.[83] For instance, the detection of lysine methylation,[84] tyrosine sulfation,[85] and tyrosine phosphorylation[86,87] has been reported. Since phosphorylation events in a biological environment correlate with protein kinase activity, this also allows enzyme activities to be determined by MS.[88]

Unfortunately, proteins containing large proportions of carbohydrates (e.g. glycoproteins) are still rather refractory to MS analysis. The problem here is that the signals of glycosylated proteins are extremely broad and reflect the large amount of heterogeneity in the carbohydrate moiety.[16] MALDI/TOF mass spectrometers are, however, generally able to resolve individual glycoforms only for small proteins containing a limited number of glycans, preferably attached only to one site. One example is ribonuclease B (15 kDa) with five mannose glycans at a single glycosylation site.

Treatment of such glycosylated proteins with specific glycosidases and the subsequent remeasurement of the mass spectra often provides useful information on the number and the chemical structure of the carbohydrates that are removed by the enzyme.[89]

Figure 7 MALDI/TOF mass spectrum of a 1 mg mL^{-1} solution of human serum albumin. For this spectrum 1 μL of protein solution (1 mg mL^{-1}) was transferred to the sample plate followed by 1 μL of matrix solution (10 mg mL^{-1} sinapinic acid in a water–ACN–TFA mixture).

A further important advantage of MALDI in the field of protein analysis is that the quaternary structure of a protein can be elucidated.[90,91] For example, the tetrameric, noncovalently bound subunits of proteins like glucose isomerase and streptavidin could be clearly detected by MALDI/TOF.[16] Dissociation and association of such complexes can easily be followed when different solvents are used. Pure water favors the association of the complexes, whereas the addition of organic (less polar) solvents such as ethanol leads to dissociation of the protein complexes.[16] This exciting application of MS is still in its infancy, but currently, the number of papers dealing with the detection of noncovalent complexes is increasing strongly.[92] Very recently, it was shown that noncovalent protein–protein complexes can be easily analyzed if neutral matrix solutions (instead of commonly acidified solutions) are used.[92] For a comprehensive review of this topic, see the excellent paper by Bolbach.[93]

Traditionally, hydrogen exchange has been used in conjunction with nuclear magnetic resonance (NMR). However, it is now also possible to use MS to measure hydrogen exchange. The method is based on the fact that each protein contains acidic hydrogen atoms capable of exchanging with the solvent (−OH, −NH, −SH). If D_2O is used as the solvent, the heavier mass of the deuterium is incorporated into the protein. This increase in mass can be easily monitored by MS.[94] By measuring the hydrogen exchange rates, conclusions can be drawn about the dynamics of the protein as, primarily, changes of the protein backbone are monitored by this technique. Therefore, this method is very useful for characterizing protein folding or unfolding as well as potential interactions between the protein and the DNA, membranes or surfaces. It is to be noted that the largest complexes studied so far by this technique were viral capsids with molecular masses of the order of 20 MDa![95]

The most important advantages of MS analysis over SDS/PAGE are the simple experimental setup (no gel has to be prepared) and the high mass resolution with enhanced mass accuracy. However, electrophoresis is, in most cases, more sensitive than MALDI/TOF, especially when the very sensitive silver-staining procedure is used.[96] The detection limit of MALDI can be illustrated using an example. A $10\,\mu g\,mL^{-1}$ protein solution can be easily and routinely analyzed and provides a sufficient S/N. Because only $1\,\mu L$ of this sample is required (cf. Table 3), about 10 ng of protein on the sample plate is sufficient for analysis. Assuming a molecular weight of 67 kDa, one can calculate that about 0.15 pmol of protein is enough for MALDI analysis. Some recent reports have shown that femtomole[97] and even attomole[98] quantities of proteins give reasonable MALDI spectra, at least under idealized conditions. However, unfortunately, the calculation above indicates that although very low amounts of analyte on the sample plate are sufficient, relatively concentrated protein solutions have to be used.

As already mentioned, MALDI/TOF is only affected to a low extent by impurities such as detergents (sodium dodecyl sulfate (SDS)) or relatively high salt concentrations and can, therefore, be used for the analysis of crude protein mixtures[99] derived, for example, by enzymatic digestion of biological tissues. As a result, perhaps the most important application of MALDI/TOF is the analysis of protein mixtures. The low amount of fragmentation products and the presence of mainly singly charged molecular ions make the interpretation of MALDI mass spectra very simple. This makes MALDI/TOF a competitor for well-established techniques of protein chemistry such as electrophoresis. For instance, it has been shown that the individual collagen types can be easily differentiated by means of MS subsequent to thermal denaturation and trypsin digestion.[100]

Unfortunately, it must be noted that most biological samples are not sufficiently concentrated for a direct MALDI/TOF mass spectrometric analysis (e.g. the enzymes released by different cell types upon stimulation).[101] Under these conditions, only highly abundant proteins like human serum albumin can be detected; the signals arising from proteins occurring in lower concentrations are suppressed by the highly abundant proteins. One of the major advantages of MALDI/TOF MS is, however, that proteins separated by classical electrophoresis can be subsequently used for MALDI/TOF analysis[102]; in this way, the advantages of protein separation and MS methods can be combined. In recent years, special interest has been paid to such applications and a number of publications on this topic are now available. Nevertheless, the main problem in the field of protein analysis is still the rather low reproducibility of MALDI/TOF mass spectra. Different approaches have been tried to improve the homogeneity of the analyte–matrix crystals, for example by the application of nitrocellulose membranes[103] and electrospray sample preparation.[104]

6.3 Carbohydrates/Polysaccharides

Whereas MALDI/TOF MS has become an established tool in protein chemistry, there are not many reports on the feasibility of MALDI/TOF for the analysis of carbohydrates.[23] This lack of experimental data is primarily because of two reasons. First, many proteins have a rather fixed molecular weight (if posttranslational modifications are neglected), whereas naturally occurring polysaccharides possess a considerable distribution of their molecular weights. This results in a decreased concentration of the individual species and, consequently,

sensitivity for carbohydrate detection is considerably diminished.[105,106] Second, many physiologically relevant polysaccharides do not occur as such, but are mostly esterified with phosphorus or sulfuric acid.[107] The resulting phosphates and sulfates possess a higher polarity than the uncharged polysaccharides, and desorption as well as ion formation is strongly decreased. Because this derivatization leads to serious problems, at least under standard experimental conditions, up to now, mainly low-molecular-weight oligosaccharides like dextran that carry no additional charges have been characterized.[106] A typical spectrum of an aqueous solution of dextran (which is a homopolymer composed of glucose residues that are mainly $1 \rightarrow 6$ glycosidically linked)[43] recorded in an aqueous DHB matrix is shown in Figure 8.

Dextran shows a mass spectrum that resembles the PEG spectrum, with the mass difference of the two individual peaks at 162 Da.[106] This value corresponds to the molecular weight of the glucose subunit (180 Da) minus one water molecule (18 Da), which is eliminated by the formation of the glycosidic linkage. Therefore, the mass spectrum can be directly used to estimate the number of repeating units of the polysaccharide although smaller molecules are more sensitively detected than larger ones. In Figure 8(b), the matrix as well as the dextran solution has been prepared in deuterated water (D_2O) to show the effects of isotope exchange. As clearly seen, the use of the deuterated solvent shifts all peaks to higher masses and multiplies the number of peaks (mass difference is 1 Da) through the competition of hydrogen and deuterium for the number of exchangeable protons within the dextran molecule. This behavior enables the operator to estimate the number of acidic residues within the polysaccharide. The theoretical basis and some applications of such exchange processes were recently discussed.[108] At the same time, the deuterium/hydrogen exchange results in a poorer signal because of increased noise owing to the lower numbers of the individual species.

Although commonly used matrices like DHB can be used for the analysis of small carbohydrates, methods for the improvement of sensitivity and resolution of saccharides are still needed. However, very recently, it has been shown that high-molecular-weight carbohydrates (~70 kDa) can also be analyzed by MALDI/TOF if an extremely high matrix/analyte ratio is used (DHB in about 10^5-fold molar excess over the analyte).[109] Unfortunately, the resulting mass resolution is extremely poor and the only information obtainable is an approximate estimation of the molecular weight. Consequently, for carbohydrate analysis, new matrix compounds yielding higher mass resolution and an enhanced S/N are essential for future applications. One recent proposal for this problem has been the use of arabinose osazone as matrix.[110,111] The idea behind this is that osazones (the reaction products between reducing carbohydrates and phenylhydrazine) are classical well-crystallizing compounds that are often used for the derivatization of carbohydrates. It is, therefore, assumed that osazones possess ideal crystallization properties in a mixture with different carbohydrates. The authors demonstrated that the use of arabinose osazone gave spectra with an improved S/N compared with spectra obtained with DHB.[110] An additional advantage of this application is the very high tolerance of the osazone matrix toward salts and other contaminants.

A very intriguing example for the MALDI/TOF analysis of complex carbohydrates was an investigation of

Figure 8 Comparison of the MALDI/TOF mass spectra of commercially available dextran (MW ≈ 1500). Both spectra were recorded with a reflectron and in the DE mode. (a) Matrix and analyte dissolved in H_2O. (b) Matrix and analyte dissolved in D_2O.

milk.[112] Although initial separation of the different carbohydrate classes was required, the authors succeeded in the identification of a large number of different, so far unknown, carbohydrates. It is especially interesting that, even under these nonoptimized conditions, polysaccharides up to a molecular weight of about 8 kDa could be detected and their structure elucidated.

It is even harder to analyze acidic polysaccharides. Although some attempts have been made to characterize strongly acidic carbohydrates such as heparin **(10)**[113,114] or CS **(11)**[115] by MS, all these studies used a previous derivatization of the carbohydrate sample to enhance desorption and volatility. For MALDI/TOF analysis of acidic carbohydrates, it is strongly recommended to add an artificial, positively charged (caused by e.g. a high arginine content) oligopeptide to the carbohydrate solution.[116] This peptide binds noncovalently to the negatively charged groups of the polysaccharide, reducing the negative charge of the analyte. The resulting ionic complexes easily desorb and can be conventionally analyzed by MALDI/TOF. However, all molecular weights have to be corrected for the (known) mass of the peptide. Comparable spectra may also be obtained by the use of positively charged spermine.[117]

Very recently, it was found that strongly acidic oligosaccharides (up to a molecular weight of about 2 kDa) can be directly characterized by MALDI/TOF. Such oligosaccharides are usually produced by the enzymatic treatment of the corresponding polysaccharide with specific or less-specific saccharidases, for example, hyaluronidase[118,119] or chondroitinase.[119,120] If this digestion is carefully performed, the reproducibility of mass spectra is high; it was shown, in the case of selected hyaluronan oligosaccharides, that quantitative evaluation of spectra is even possible.[121] In Figure 9, some selected spectra of HA-6 recorded at different concentrations are shown.

The spectra (A) correspond to the positive ion spectra, whereas spectra (B) represent the negative ion spectra. It is obvious that the negative ion detection mode is more sensitive: considering the lowest concentration of HA-6 (traces, Figure 9c and f), the positive ion (Figure 9c) spectrum is characterized by a poor S/N ratio that is close to the detection limit. It is also to be noted that the peaks detectable in Figure 9(a) (marked with asterisks) at $m/z = 1233$ and 1245 are not caused by HA, but are stemming from the applied DHB matrix ($7\,\mathrm{DHB} - 6\,\mathrm{H}^+ + 7\,\mathrm{Na}^+$). It is well known that DHB, under conditions of laser irradiation, gives some charged oligomers.[122] By defining any arbitrary S/N ratio as threshold, detection limits can be easily obtained. Selected data are shown in Figure 10:

It is evident that the detectability decreases when the mass of the HA of interest increases, indicating that larger amounts are required when HA oligosaccharides with higher masses are investigated. It is also clear that this effect is more pronounced if the positive ion spectra are analyzed: since each polymer repeat unit (composed of one glucuronic acid and one *N*-acetylglucosamine unit) adds one negative charge, the sensitivity difference between the positive and negative detection mode increases if the mass of the investigated HA increases.[121]

Figure 9 Positive (A) and negative ion (B) MALDI/TOF mass spectra of aqueous solutions of HA-6 relative to the amount of HA on the MALDI target. Solutions of 3.13 ng (a,d), 0.41 ng (b,e), and 0.05 ng (c,f) were deposited onto the sample plate. All spectra were recorded in the linear detection mode for optimum sensitivity. All peaks are marked according to their individual m/z ratios. Peaks arising from the DHB matrix are marked with asterisks. (Figure was published in ref. 121, © Elsevier 2006.)

Figure 10 Detection thresholds (amount of HA on the sample plate) relative to the size (number of monosaccharide units) of the individual investigated hyaluronan fragments. The deviations were estimated to be of the order of ±5%. An S/N ratio of 3:1 was regarded as the detection limit. It is to be noted that the considerable deviations between positive and negative detection mode when HA fractions with a higher molecular weight were investigated. (Figure was published in ref. 121, © Elsevier 2006.)

Since our group is mainly interested in the investigation of degradation processes of the extracellular matrix of cartilage during rheumatic diseases, the analysis of negatively charged oligosaccharides would be of great significance for progress in this field. It is known that the strongly acidic polysaccharides of cartilage (HA, CS, and keratan sulfate) are depolymerized during inflammation, under the influence of reactive oxygen species (ROS)[49] and different enzymes.[123] Owing to the large variety of ROS and enzymes that both occur under in vivo conditions, however, the investigation of such processes is very difficult. Nevertheless, MS has proven usefulness for the investigation of degradation processes of polysaccharides of cartilage by ROS on a model level.[124] However, one should always keep in mind that a direct analysis of acidic carbohydrates with molecular weights higher than a few kilodaltons is impossible, and details of previous enzymatic degradation are necessary to obtain defined oligosaccharides. A similar approach based an ESI MS and selective enzymatic digestion was also used to analyze the hyaluronan content in CS preparations.[125]

One promising approach for the cure of degenerative joint diseases is the transplantation of stem cells or chondrocytes (the cartilage cells that synthesize the extracellular matrix) into the joint of the affected patient to replace the damaged cartilage. An alternative is the transplantation of bioengineered cartilage and this interesting topic has been recently reviewed.[126] Unfortunately, it is very difficult to assess under which conditions chondrocytes generate a maximum of extracellular matrix, as the standard histological approaches provide only a semiquantitative information. It was shown recently that the de novo synthesis of CS may be easily determined by MALDI/TOF MS subsequent to cartilage degradation by chondroitinase ABC (an enzyme that cleaves CS A, B, and C) that produces a single unsaturated disaccharide from the CS of cartilage that can be very easily monitored by means of a positive and – more sensitive – negative ion MS.[127] In these studies, it could be shown that not only the amount of CS can be easily determined but information on the ratio between the 4- and the 6-sulfate isomer (that occur both under in vivo conditions) can also be obtained, as the fragment ion spectra from the 4- and the 6-sulfate isomer differ significantly.[128]

This is schematically shown in Figure 11.

Chondroitin sulfate was completely digested with chondroitinase ABC and the negative ion spectra directly recorded from the digest. The protonated and the sodiated forms of the resulting unsaturated disaccharide are shown in Figure 11. Both ions were subjected to further PSD analysis: it is obvious that both spectra differ considerably, although the same molecule, but only different adducts are analyzed. In particular, the peaks at $m/z = 282$ and 300 that appear exclusively in the upper spectrum are of interest because they are derived exclusively from the 6-sulfate and the 4-sulfate, respectively. The reference data were obtained by using electrospray ionization/collision-induced dissociation (ESI/CID).[128] However, such a sophisticated equipment is obviously not absolutely required, as the same information can be also obtained by using the simple PSD technique that is routinely available on all MALDI devices equipped with a reflectron.[129]

However, this method has some disadvantages too: for instance, PSD suffers from relatively low sensitivity, and only moderate resolution can be obtained. Additionally, the need to stitch together spectra derived from several reflector voltages makes calibration rather difficult. It is also important to note that the extent of fragmentation depends significantly on the applied matrix. ''Hot'' matrices such as α-cyano-4-hydroxy cinnamic acid (4-HCCA) usually catalyze considerable fragmentation, whereas ''cooler'' matrices as DHB or Trihydroxyacetophenone (THAP) do not. A more comprehensive discussion of this aspect was provided by Pfenninger et al.[130]

In summary, so far the main application of MALDI/TOF in the field of carbohydrate research is for the analysis of well-defined carbohydrates occurring in complex molecules such as glycolipids or glycoproteins. There are only few reports on the analysis of naturally occurring, acidic oligo or polysaccharides. The main problem, besides the distribution of molecular weights,

Figure 11 Negative ion post source decay (PSD) MALDI/TOF mass spectra of chondroitin sulfate digested with the enzyme chondroitinase ABC. The fragmentation of the protonated and the sodiated parent ions was investigated. It is to be noted that both spectra are clearly different and provide some peaks allowing the assignment of the 4- and the 6-sulfate. For further details see the articles by Schulz et al.[127] and Zaia et al.[128]

is the low extent of desorption of carbohydrates, leading to low sensitivity. We hope that these difficulties can be minimized by the application of new matrix compounds and further developments in MS devices.[131,132]

6.4 Lipids

Although the importance of lipids has tended to be overlooked, interest has recently increased with the realization that rarer lipids have important roles in biological modulation.[133] While common PLs like PC **(2)**, PS **(1)**, and PE **(3)** are essential constituents of the cell membranes,[38] rare lipids like phosphatidylinositol phosphates **(4)**, DAGs **(6)**, and PA **(5)** are assumed to play a very important role in signal transduction processes.[40] Finally, highly unsaturated fatty acids, e.g. arachidonic acid, are important for the synthesis of essential molecules like prostaglandins or leukotrienes.[24]

Whereas nearly all available ionization methods of MS have been already used in MS lipid analysis, nowadays, only two of them play a major role, namely, ESI[134] and APCI[135] (atmospheric pressure chemical ionization). Reviews on the advantages and drawbacks of the individual methods are also available.[1] MALDI/TOF

MS is also increasingly used in the field of lipid analysis, although it took some time to explore the advantages and capabilities of this method after some pioneering studies in the middle of the 1990s.[136,137] This is somewhat surprising, as the most important requirement of MALDI/TOF MS, an even crystallization of analyte and matrix, is fulfilled by lipids: these apolar molecules are insoluble in water and, therefore, all operations may be performed in organic solvents only, where a majority of common UV MALDI matrices are also easily soluble. This provides very homogeneous analyte–matrix crystals. In Figure 12, two different wells on a MALDI sample plate containing crystals of an aqueous analyte–matrix mixture and an organic analyte–matrix mixture are shown.

Figure 12(a) shows a typical example of a carbohydrate–matrix (aqueous DHB) mixture with uneven crystallization; Figure 12(b) shows a lipid–matrix mixture for which a 1-μL sample of lipid in chloroform was transferred to the sample plate, and a 1-μL droplet of the matrix solution (DHB in methanol) was subsequently added. It is clear that the latter mixture provides by far more homogeneous crystallization accompanied by good shot-to-shot reproducibility.

Figure 12 Comparison of two different wells of the MALDI sample plate. (a) The crystallization pattern of a typical aqueous carbohydrate sample with DHB as matrix. (b) A typical dried mixture of DHB (0.5 M in methanol) and a lipid, crystallized from chloroform.

To give the reader an idea about typical spectral patterns of lipids, some selected positive and negative ion (indicated by "+" and "−") MALDI-TOF mass spectra of three physiologically relevant PLs (PC 16:0/18:1, PE 16:0/18:1, and PS 16:0/18:1) as well as triolein are shown in Figure 13.

Considering first the positive ion spectra, significant differences are obvious: PC 16:0/18:1 provides two peaks

Figure 13 Selected positive and negative ion (indicated by "+" and "−") MALDI-TOF mass spectra of three physiologically relevant phospholipids (PC 16:0/18:1, PE 16:0/18:1, and PS 16:0/18:1) as well as triolein. It is to be noted that all lipids are detectable as positive ions, whereas only acidic lipids provide significant yields of negative ions. The more marked contribution of matrix signals (marked with asterisks) to the negative ion spectra is obvious. In the inserts labeled "a" and "b", the expanded regions of the peak at $m/z = 551$ and 784.6 are shown. It is obvious that the different chemical formula of the DHB matrix and the lipid are clearly reflected by the distribution of the isotopes.

at $m/z = 760.6$ and 782.6 according to the H^+ and the Na^+ adduct of the neutral PC molecule. There are no further signals that would point out fragmentation. This is in agreement with our previous work[25] and the work from other groups.[138] There are not even traces of lysophosphatidylcholine (LPC) that is generated from PC by the loss of an acyl residue. This makes MALDI a useful tool to determine LPC – an important lipid second messenger – in biological samples.[139]

In contrast, the spectrum of PE 16:0/18:1 is more difficult to interpret. This is amazing, since PC as well as PE are both zwitterionic lipids with comparable properties. However, one must consider that PE possesses a $-NH_3$ group with exchangeable protons[25]: the peaks at $m/z = 718.5$ and 740.5 correspond to the H^+ and the Na^+ adduct of the PE as in the case of PC. In contrast, the peak at $m/z = 762.5$ corresponds to an exchange of one H^+ by Na^+, i.e. this peak can be assigned to $PE - H^+ + 2Na^+$. Additionally, in contrast with PC, the PE has a higher tendency to lose its polar head group, and this results in the peak at $m/z = 577.5$. The same fragment (but with lower intensity) is also detected in the case of PS 16:0/18:1 that possesses the same fatty acyl composition as the PE. In the case of the PS, different adducts ($m/z = 784.6$, 806.6, and 828.6) are also detected. This is not surprising, as the PS is an acidic PL and there are different possibilities to compensate its negative charge to obtain a singly charged positive ion. A survey of the mass spectrometric properties of different lipid classes was recently published[25] and their tendency to give fragment ions was discussed.[140] It is notable that the different adducts of a certain lipid have different tendencies to give fragment ions.[42] For instance, it was shown in the example of PC that the Na^+ adducts give much more fragment ions and are, therefore, much more useful for structural investigations than the corresponding H^+ adducts that are dominated by the loss of the polar headgroup.[138] A similar investigation is also available for the fragmentation behavior of PE.[141]

Surprisingly, the triolein does not give a mixture of H^+ and Na^+ adducts, but the Na^+ adduct is exclusively detected at $m/z = 907.8$. Although this behavior of triacylglycerols (as well as DAGs)[56] is well known,[142] only very recently, a potential explanation has been provided.[143] It has been suggested that the H^+ adducts are generated in similar amounts as the Na^+ adducts. However, their stability is much lower in comparison to the Na^+ adducts. Accordingly, the H^+ adducts do not "survive" the TOF distance and yield the fragment ion clearly detectable at $m/z = 603.5$ corresponding to the loss of one acyl residue. Consequently, to decrease the yield of fragment ions, it has also been suggested to perform the sample preparation under alkaline conditions, where the yield of H^+ adducts is much lower.[143]

Generally, the yield of alkali adducts depends strongly on the alkali ion content of the sample. This means, for example, that Na^+ adducts may be replaced by K^+ adducts when an excess of K^+ is added to the lipid solution.[24] This may also be useful when problems with overlapping peaks (H^+, Na^+, and differences in acyl compositions) have to be solved, although, in that case, the use of Cs^+ seems still more advisable.[144]

Generally, the negative ion mode is less frequently used for the characterization of lipids. There are two reasons: (i) not all lipids are detectable as negative ions and (ii) the matrix (DHB is most often used for lipids)[25] provides more intense signals in comparison with the positive ion spectra.[58] Accordingly, because the triolein does not possess acidic groups, it is not detectable as negative ion. The detected signals at $m/z = 681$ and 857 are caused by oligomerization of the applied DHB matrix.[122] Of course, PS ($m/z = 760.6$) and PE ($m/z = 716.5$) can also be detected as negative ions because of their exchangeable protons, respectively. Surprisingly, there are additional peaks at higher masses, for instance, at $m/z = 892.5$ in the case of the PE.[141] This signal is caused by a cluster ion between the lipid (detected as negative ion at $m/z = 716.5$) and the applied DHB matrix (atomic mass of the corresponding sodium salt: 176). Although the formation of matrix ion clusters was not yet comprehensively studied, it is of interest to note that such clusters with PC enable the detection of PC as negative ion at $m/z = 912.6$.[145] This cluster ion formation seems a unique feature of DHB, because by using other matrix compounds as 2,4,6-trihydroxyacetophenone[146] or *para*-nitroaniline (PNA),[147] matrix lipid clusters could not be observed.

Generally, the presence of PC in lipid mixtures in similar amounts as other lipids causes problems, as PC is very sensitively detectable as positive ion because of the permanent positive charge of its choline headgroup. Therefore, its presence may lead to the suppression of the signals of further lipid classes.[122] Unfortunately, this does not only hold for the positive ion detection mode but the detection of negatively charged lipids as negative ions is also influenced by the presence of PC.[148] A detailed investigation of the detection limits of different important PLs was reported by Gellermann et al.[149]

Although the preferred detection of lipid classes with quaternary ammonia groups (PC, sphingomyelin, and the corresponding lysolipids) may also be regarded as an advantage because the spectra are significantly simplified if only selected lipid classes are detected, this is simultaneously a disadvantage: previous separation into the individual lipid classes is required if a more detailed lipid analysis is to be performed. As thin-layer

chromatography (TLC)[150] is an established analytical tool in lipid research, there is an increasing interest in the direct coupling between MALDI and TLC, enabling the direct detection of PLs on the TLC plate subsequent to separation. Such approaches were already established for glycolipids,[151] but only minor attempts were made to develop a suitable method of PL analysis by direct MALDI/TLC coupling.

Two different approaches are so far available: the first one used a home-built orthogonal MALDI/TOF device with an IR laser[152] and glycerol as matrix, whereas the second approach applied a commercially available device equipped with a UV laser.[153] Both reports indicated comparable sensitivities and resolutions. The use of the dye primuline is recommended for staining the individual lipids on the TLC plates because this dye does not bind covalently to lipids and, therefore, does not alter their molecular weights.[154]

Quantitative analysis of MALDI/TOF mass spectra of lipids can be performed by three different methods[25]: (i) by the use of a known internal standard, (ii) by the comparison of the peak intensity of the analyte with a known matrix peak, or (iii) by using the S/N ratio.[155] Method (i) seems most suitable for DAG[56] and PC analysis, whereas (ii) has so far been only used for apolar lipids, especially triacylglycerols.[142] Finally, method (iii) is suitable for the analysis of acidic PLs, e.g. phosphoinositides,[148] and lysophospholipids.[155] Nevertheless, the determination of absolute amounts of different PL classes in mixtures by MALDI/TOF MS is still difficult and spectroscopic techniques as ^{31}P NMR seem superior for that application.[156]

There are obviously several important applications of lipid analysis by MALDI/TOF MS. First, the rough lipid composition of an unknown sample can be easily and quickly estimated. To achieve this, the sample is extracted by known procedures with mixtures of methanol and chloroform, plus hydrochloric acid, if more polar lipids have to be investigated.[157] After separation of the organic and the aqueous layer, the chloroform layer can be immediately applied to the MALDI target without any further purification, since common impurities like salts and buffer components remain in the aqueous layer. However, the organic layer should be washed several times with distilled water.[66]

In Figure 14, this technique was applied to obtain PL profiles of different cell lines (murine stem cells, astroglia, and rat hepatoctyes) and one selected tissue (human liver). Both, positive (A) and negative (B) ion spectra are shown and it is obvious that a clear differentiation of all samples can be easily made at the first glance.

As already indicated above, the detection of PE in mixtures is a major problem as this PL is only scarcely detectable as negative ion,[141] but is suppressed in the positive ion mode by lipids with quaternary ammonia groups that are more sensitively detectable.[122] To be

Figure 14 Positive (A) and negative (B) ion MALDI-TOF mass spectra of organic extracts of murine stem cells (a), astroglia (b), rat hepatoctyes (c), and human liver (d). All spectra were recorded with *para*-nitroaniline (PNA) as matrix. To minimize peak overlap between H^+ and Na^+ adducts on the one hand, and differences in fatty acyl compositions on the other, all solutions were saturated with CsCl.[144]

able to detect PE in the negative ion mode and to avoid suppression effects of further negatively charged PL (e.g. phosphatidylinositole (PI) at $m/z = 885.6$)[148] or PL with quaternary ammonia groups, PNA was used as matrix.[147] Furthermore, for the detection of positive ions, an excess of CsCl was added to the matrix solution to assign peaks unequivocally and to avoid overlap between H^+, Na^+, and K^+ adducts of lipids with different acyl compositions.[144]

The mass spectra of the murine stem cells indicate the most pronounced diversity of PLs, particularly in the positive ion mode. Furthermore, stem cells contain high amounts of ether-linked PL (cf. the peaks at $m/z = 878.5$, 900.5, and 928.5) and highly unsaturated acyl chain residues (the peak at $m/z = 942.5$, for instance, represents PC 18:0/20:4). It is obvious that such compounds are nearly completely absent in the spectrum of the astroglia (Figure 14b). In contrast, the mass spectrum of the astroglia extract contains a significant concentration of PC 16:0/16:0 ($m/z = 866.5$) that is rather typical of this cell line and represents a completely saturated lipid species. In the same way, the positive ion spectra of hepatocytes (Figure 14c) and the human liver extract (Figure 14d) can be easily differentiated. It is also obvious that the negative ion spectra allow a very fast estimation of the PE content: for instance, astroglia (Figure 14c) have only a very small PE content, whereas the liver (Figure 14d) and the stem cells (Figure 14a) possess a significant portion of PE, particularly PE 18:0/20:4 ($m/z = 766.5$).

Although from this simple approach only a limited extent of information can be obtained, this type of analysis can be performed within a few minutes and, therefore, information on crude sample composition can be obtained in a very fast and convenient way. Many further cell and tissue extracts were already investigated in this way, including granulocytes,[24] human spermatozoa,[158] animal spermatozoa (bull),[159] and synovial fluid as well as serum[160] from patients suffering from rheumatoid arthritis. A small textbook with the molecular weights of many relevant lipid classes and selected mass spectrometric properties of lipids is also available.[161]

Finally, it should also be noted that MALDI/TOF MS analysis is not limited to organic extracts, but tissue slices may be also directly analyzed. For instance, Jones et al. have shown by analyzing different tissue sections of mouse brain, heart, and liver by MALDI Fourier-transform mass spectrometry (FTMS) that the quantitative data on lipid composition are superior in comparison to chromatographic reference data and provide higher accuracy.[162] Although reports on ''whole cell'' lipid analysis are also available,[163] there is so far only a single paper dealing with ''whole animal'' analysis. *Daphnia Galeata* with a diameter of a few millimeters were analyzed by MALDI/TOF MS by placing the animals directly onto the sample plate.[164] Although reasonable spectra could be recorded allowing the assignment of many lipids, a rather poor S/N ratio was obtained because of poor sample purity.

Another important application of lipid analysis by MALDI/TOF MS is the examination of reactions accompanied by lipid peroxidation, which was primarily performed by ESI in the past.[165,166] It is well known that lipids containing double bonds react quickly with ''ROS'' like hypochlorite[167] or hydroxyl radicals ($HO^{\bullet}$) under the formation of (to a greater or lesser extent) characteristic products.[168]

To investigate such reactions, MALDI/TOF analysis is very useful, because it can provide fast information on molecular weights and quantitative information on the extent of lipid modification.[169] As a typical example, the conversion of PC 18:0/18:1 (its monoisotopic mass is 785.6) to the corresponding chlorohydrine under the influence of the HOCl-generating system myeloperoxidase–H_2O_2–Cl^- is shown (Figure 15). Myeloperoxidase (MPO) is the enzyme that catalyzes the generation of HOCl from H_2O_2 and Cl^- under inflammatory in vivo conditions.

It is evident that chlorohydrine formation[169] can be easily followed by the increase of the peak at $m/z = 840.6$, which corresponds exactly to the molecular mass of the product expected upon the addition of hypochlorous acid to PC 18:0/18:1 (788.6 + 52 (HOCl)), if only the main abundant isotope of chlorine (^{35}Cl) is used for the calculation.[168] As expected, the corresponding Na^+ adduct is also detectable at $m/z = 862.5$. Further studies have also provided evidence that besides the chlorohydrines, LPC (lacking the unsaturated fatty acyl residue) is also generated by the reaction of PC with HOCl.[170] However, the content of double bonds in the unsaturated fatty acyl residue seems to determine the yield of LPC: docosahexaenoyl residues (22:6) provide the most pronounced LPC generation, whereas oleoyl (18:1) residues provide only small amounts of LPC.[170] Similar studies were also performed with plasmalogens that can – despite their rather labile alkenyl ether group – also easily be characterized by MALDI-TOF MS.[171] It must be stressed, however, that the addition of acid (to enhance the yield of H^+ adducts) to the matrix must be strictly avoided, as plasmalogens are extremely sensitive to even traces of acids and decompose under the generation of LPC.[159]

The very last comment on the analysis of lipids seems trivial, but neglecting this fact may give rise to a number of serious problems. This problem concerns details of the handling of the lipid samples. Lipid analysis usually requires the use of chloroform as solvent. Compared with most other widely used solvents, $CHCl_3$ is a rather aggressive chemical that reacts with many

Figure 15 Changes in the mass spectrum of 1-stearoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (trace (a)) after incubation with the myeloperoxidase–hydrogen peroxide–chloride system at pH 6.0. Phospholipid liposomes (0.03 mg mL^{-1}) prepared in 0.14 mol L^{-1} NaCl, 50 mmol L^{-1} phosphate were incubated with hydrogen peroxide (three additions of 0.1 mmol L^{-1} in intervals of 10 min) and MPO (35 nmol L^{-1}) for 60 min (b) or 120 min (c). In trace (d), all additions of MPO and hydrogen peroxide have been repeated after 1 h. The total incubation time in sample (d) was 2 h. All concentrations are final ones. (Figure was published in ref. 169, © Elsevier 2001.)

substances, including polymers. Therefore, it is strongly recommended to avoid any plastic material and to use exclusively glassware as reaction vessels. Additionally, glass syringes instead of plastic pipette tips, should be used. Figure 16 shows the MALDI/TOF (positive ion) mass spectra of $CHCl_3$ in which colored pipette tips had been stored for a few minutes.

The yellow pipette tip particularly (trace in Figure 16a) results in a number of impurities; these most likely correspond to the plasticizers in the material of the pipette tip. This fact should be carefully taken into account even if the molecular weights of the impurities do not fall into the range of the substances of interest. Since such plasticizers give a strong signal, particularly for the positive ion spectra, the intensity of the peaks of interest is considerably diminished.[66]

6.5 Other Compounds

Some studies have examined the feasibility of MS for the investigation of nucleic acids,[172] especially of smaller oligomeric units of ribonucleic acid (RNA).[173] These

Figure 16 Positive ion MALDI/TOF mass spectra of standard pipette tips, which were incubated for a few minutes with chloroform: (a) extract of yellow tips; (b) extract of blue tips.

compounds are rather difficult to analyze because they are characterized by a significant negative charge density caused by their phosphate residues. Therefore, low ion yields, fragmentation, and signal heterogeneity due to multiple cationization of the phosphate backbone are the main problems that need to be solved for successful performance. Although there are an increasing number of reports on this topic,[174] its comprehensive treatment is outside the scope of this article.

Many studies available so far have used IR lasers as the ionization process by IR MALDI, which is known to be softer in comparison with UV MALDI.[35] Using IR MALDI, DNA samples up to about 20 kDa have already been successfully analyzed.[175] If UV MALDI is to be used, 3-HPA (3-hydroxy-picolinic acid) is the matrix of choice for DNA analysis. Surprisingly, the yield of positive and negative ions is comparable despite the considerable negative charge of DNA and RNA if 3-HPA is used.[176] Nevertheless, sample preparation is still more important than in the case of other substances.[177]

The MALDI/TOF analysis of other substance classes, for instance, carotenoids and analogous compounds, is described elsewhere.[178]

6.6 Matrix-assisted Laser Desorption/Ionization Imaging

Over the past decade, a new analytical method ''MALDI imaging'' for examining biological samples and for visualizing analytical information has evolved.[179] Clearly, this topic is out of the scope of the present article, but some comments seem necessary. For a more detailed review see the article by McDonnell and Heeren.[179]

This new technique allows one to visualize the two-dimensional concentration profiles of defined biomolecules in or on the surface of biological samples, and it is expected to have a great impact on, for example, proteomics and metabolomics research in the future because of the available spatial resolution. One should, however, also note that such attempts have been performed since many years and are, therefore, not completely new. Even about 30 years ago, soon after powerful UV lasers first became commercially available, a new method was developed that permitted the mass spectrometric analysis of biological material, by using a highly focused laser beam.[180] This ''laser microprobe mass analysis'' (''LAMMA'') technique already provided a spatial resolution of about 1 μm and not much progress was made as modern ''MALDI imaging'' devices (using nitrogen lasers with $\lambda = 337$ nm) could provide a resolution of only about 0.6 μm.

Although resolution seems quite limited in comparison with modern microscopic techniques, there are some recent encouraging applications. For instance, by imaging studies of human glioblastoma slices, it is possible to differentiate the tumor region from the ischemic and necrotic areas of the lesion on the basis of localization of different proteins.[181] Very recently, ''MALDI imaging'' has also been successfully used to differentiate normal from the cancerous regions of man's prostate by evaluating specific protein expression patterns.[182] From these examples, it seems most likely that MALDI imaging will have a great future development.[179]

7 QUALITY OF MASS SPECTRA

Usually, a ''good'' mass spectrum should exhibit an excellent mass resolution and a reasonable S/N.[183] However, every user must decide what information is most important, since the resolution can be – at least to a certain extent – compromised for increased sensitivity and vice versa.

7.1 Mass Resolution and Mass Accuracy

Reasonable mass resolution is often of particular importance, for example, to derive the elemental composition of an unknown compound. This is of particular relevance if the masses of peptides obtained by enzymatic hydrolysis of an unknown protein are assigned by database searching.[35] If mass accuracy is relatively low, many potential peptide structures are obtained. The higher the mass accuracy, the lower is the number of ''hits'' in the database! Unfortunately, highly resolved mass spectra cannot be routinely acquired and require the use of sophisticated – and expensive – mass spectrometers, for instance, equipped with FTICR (Fourier transform ion cyclotron resonance). A more detailed description of this technique, which was recently reviewed, is outside the scope of this article.[184]

Independent of the mass analyzer, each user of a mass spectrometer should be aware that the number of sampled data points is essential for high resolution. For example, if one wants to determine the mass of an unknown substance with an accuracy up to the third decimal point, at least 1000 data points/Da are required to achieve this. This means that for highly resolved mass spectra, the mass range must be minimized to obtain a sufficient number of data points. Commercially available MALDI/TOF devices provide mass resolutions of a few thousand (linear mode) up to about 20 000 in the reflectron mode under DE conditions.[35] This indicates that mixtures of molecules with monoisotopic masses of 1000 and 1000.05 can still be resolved. The mass accuracy of many commercial devices is of the order of 20 ppm, i.e. if a compound with a mass of 1000 Da is investigated, the mass can be provided with 1000 ± 0.02. One should also note that changes of the

instrument settings to increase sensitivity (e.g. increasing the reflectron voltage) require new calibration of the instrument.[35]

High mass resolution is not only important for the assignment of unknown peptides obtained by digestion of proteins, but is also typically required to determine whether a peak in a lipid spectrum, for example, corresponds to a K^+ adduct (M + 39) or the Na^+ adduct of the corresponding epoxide (M + 23 + 16). Since each possibility leads to slightly different masses (M + 38.9637 or M + 38.9847), exact mass determinations would allow the clear discrimination of both compounds.

However, the same information can also be obtained by a simple exchange experiment, using an excess of K^+ or Cs^+ [144] instead of Na^+.

7.2 Signal-to-noise Ratio

A reasonable S/N is highly desirable, for example, to identify low amounts of a certain compound of a mixture. Improving the S/N is a rather empirical process since it depends on a number of parameters that have to be carefully set. Such parameters include the analyte concentration, the matrix concentration, the analyte/matrix ratio, the applied laser intensity, the parameter setup, and so on. Here, for each substance and each sample, one has to find individually the best conditions. However, MALDI/TOF differs in a certain respect from most other analytical methods: an enhancement of the sample concentration does not necessarily increase the S/N. If the matrix/analyte ratio reaches a suboptimal level, the signal of the analyte is strongly suppressed![25]

7.3 Observed Fragmentations

In contrast with classical (EI) MS, where the inspection of fragmentation products mainly allows conclusions on chemical structure, in MALDI/TOF methodology the extent of fragmentation can be kept to a minimum and, usually, the (quasi) molecular ions provide the most important information. Therefore, some caution is needed not to obscure the molecular ion. In particular, the matrix should always be present in a large excess over the analyte to prevent a ''direct hit'' of the laser on the analyte, which would cause degradation of the sample.[24] It is also a widespread error that increased laser intensity leads to an improved S/N. In most cases, enhanced laser intensity is accompanied by a strong distortion of the baseline,[56] which may prevent the observation of small quantities of analyte. Basically, using a different matrix and changing the pH of the applied solutions slightly may be sufficient to decrease the extent of fragment ion generation.

7.4 Troubleshooting

If the acquired mass spectra are not in accordance with the expected sample composition, or, even worse, no signal at all can be detected, there are a few general changes that can be tried.

For most mass spectra, the average of a fixed number of different laser shots is calculated. It is possible to observe the individual spectra and try to lead the laser beam to a ''hot spot''. However, it may happen that all analyte on the sample plate has been spent (in some cases, the ablation from the sample plate can be seen). If this occurs (usually after about 30 ''shots'' on the same spot), the laser beam should be moved to a new point on the sample plate or more analyte should be applied to the sample plate.

A serious problem (especially in aqueous samples) is the disturbing effect of impurities. If the degree of contamination with salts, buffers, or detergents is not known, the following procedure is recommended. Prepare a comparably concentrated reference sample (e.g. $1\,mg\,mL^{-1}$ serum albumin in pure water). This sample should give an intense, reproducible signal. Dilute the albumin sample with distilled water and with the sample of interest, and record the mass spectra. If the spectra differ markedly in signal intensity and mass resolution, the sample is contaminated and should be purified before further analysis. Dialysis, microdialysis, or applying ZipTips™ are often already sufficient to overcome this problem. Apolar impurities like detergents can be easily removed by binding to commercially available apolar beads. It is also important to note that the ''limit of detection'' (LOD) is mainly limited by the level of chemical background noise and hence, cannot be improved significantly by averaging over a larger number of laser exposures.[152]

8 COMPARISON WITH OTHER MASS SPECTROMETRIC METHODS

Although, in the opinion of these authors, the MALDI/TOF technique is superior to other MS techniques in many respects, it must also be compared with other MS methods for advantages, drawbacks, and applicability (Table 1).

Ionization of the sample by EI[2] provides well-reproducible and simple-to-quantify mass spectra, but also a high extent of fragmentation. This is the reason why the molecular ion is only rarely detected (or is very weak).[3] Most ionization techniques also exhibit this problem and are, therefore, not suitable for the analysis of high-molecular-weight compounds exceeding masses of a few kilodaltons. However, EI is still the

ionization of choice for quantitative investigations, and gas chromatography/mass spectrometry (GC/MS) is still a very important method. The reason is that EI generates radical cations. The yield of these radical cations depends primarily on the available functional groups within the analyte. In contrast, using ionization methods that give ''quasimolecular'' ions under the addition of cations to the analyte, the ion yield is much more dependent on the acidity or basicity of the analyte. This is the reason why internal standards should always be used for quantitative investigations by MALDI or ESI MS.

Both MALDI and ESI represent ''soft-ionization'' techniques giving only very minor degradation of the sample,[16] and both these techniques are further compared. ESI generally provides more accurate mass information on low-mass compounds than MALDI and can be very easily combined with chromatographic techniques. By comparison, MALDI is more sensitive in many cases, can also be applied to very large biomolecules (larger than 100 kDa as TOF detectors basically enable an unlimited mass range), and is relatively insensitive toward salt concentrations in the millimolar range. Additionally, MALDI yields simpler spectra, since ESI produces a number (20 or more) of molecular ions, from which the mass of the analyte can be calculated. The ESI process seems softer than MALDI and ESI has also the considerable advantage that the analyte is investigated in solution, whereas for MALDI cocrystallization with the matrix is required. Labile molecules may not survive this procedure and this is why the analysis of noncovalent complexes is still a domain of ESI MS.[185]

Both methods, MALDI and ESI, often give complementary information. Therefore, it is more beneficial to ask ''Can I use both methods to obtain an optimum of information?'' rather than to ask ''Which method should I use?''.

9 SUMMARY AND METHOD DEVELOPMENT

The most important fundamentals of MALDI/TOF MS have been described, and its applicability to the investigation of different selected substance classes has been discussed. The comparison between MALDI and ESI has been emphasized because these relatively new methods are both ''soft-ionization'' techniques that yield information mainly on the intact molecular ion. This makes both methods very suitable for the analysis of mixtures. However, it must be considered that ion yields may differ from compound to compound, and less sensitively detectable compounds may be suppressed by more sensitively detectable ones.

One of the most important applications of MALDI/TOF is protein analysis, very often in combination with other biochemical methods prior to MALDI analysis. Proteins with a molecular weight close to 1000 kDa have already been successfully characterized.[101,186] Subsequent to an enzymatic digestion of the protein, MALDI is especially well suited for so-called peptide mapping. The high sensitivity and the adequate mass resolution of MALDI/TOF make it a strong competitor for classical electrophoresis. The most current trend in this field is automatization. Mass spectrometers will soon achieve complete, nearly fully automated, sequence analysis of proteins. However, a major drawback is the still relatively low reproducibility of MALDI/TOF mass spectra owing to the limited homogeneity of crystallization between the matrix and the analyte. Here, the search for further useful matrices is essential.

In comparison with protein analysis, there are by far fewer applications of MALDI/TOF for the analysis of carbohydrates[23] and lipids.[25] Whereas lipids can be very easily and accurately characterized, carbohydrates are still a major problem. Acidic carbohydrates, particularly, show a very weak tendency to desorb and are, therefore, very difficult to analyze. To solve these problems, some efforts are necessary, and the search for suitable matrices has to be continued. Further developments in MALDI/TOF MS will follow increasing knowledge of the matrix and its interaction with the analyte.[2,11]

At present, a major drawback in the field of MALDI MS is the limited, quantitative analysis of MALDI/TOF mass spectra. Although there were some recent reports on this,[56,74] one major problem is still the limited homogeneity of the cocrystals between matrix and analyte. Further experimental progress is expected in this area as this would be also important to establish MS imaging as a reliable diagnostic tool.[179]

ACKNOWLEDGMENTS

The authors wish to thank all colleagues and friends who helped them in writing this article. We especially wish to thank Dr Holger Spalteholz, Dr Jacqueline Leßig, Dr Matthias Müller, and Ms Rosmarie Süß. The kind and helpful advice of Dr Suckau and Dr Schürenberg (Bruker Daltonics, Bremen) is also gratefully acknowledged.

This work was supported by the German Research Council (DFG Schi 476/5-1, Schi 476/7-1 as well as the former HBFG program enabling the purchase of a Bruker ''Autoflex'' device) and the Federal Ministry of Education and Research (Grant BMBF 0313836).

Nuclear magnetic resonance (NMR) spectroscopy exploits a property of the nucleus known as nuclear spin, which exhibits angular momentum and as such generates a local magnetic field that can be influenced by a larger static external field. In the presence of a large external magnet, the nuclear spins align with the field, with a slight excess opposed to the field. That small excess can be flipped to alignment with the field in the presence of a radiofrequency (RF) pulse of appropriate frequency. Relaxation of those spins back to the ground state results in emission of RF radiation whose frequency is an indication of the local electron density of the molecule in which the spin resides. Such information can ultimately be directly related to molecular structure. NMR spectroscopy is unique in that it can be used to image the whole human body at one extreme, and determine the three-dimensional (3D) structure of a biomolecule within the body at the other extreme. The principal advantages of NMR are that: (i) the complete molecular structure can be determined; (ii) the technique spans all principal states of matter (solid, liquid, gas); (iii) the method is nondestructive and can be used noninvasively, as in a clinical setting. The principal disadvantages of NMR are that: (i) the technique is very insensitive (typically samples below 50 μM are difficult to study, although recent advances in nanoprobe and cryprobe technology are rapidly revising these numbers); (ii) in liquids there are molecular weight limits of around 50 kDa – although there are new methods being developed that may have a significant impact on this; (iii) in solids only limited structural information can be obtained to date.

1 INTRODUCTION

1.1 How Nuclear Magnetic Resonance is Used to Study Biomolecules

The methods of NMR spectroscopy have proved to be an essential analytical method for the determination of the structures of biomolecules, and in the study of biomolecular function. This article provides an overview of the principal NMR methods that can be employed in structure–function studies of biomolecules, with the main focus on structure determination. Many texts discuss these topics in greater detail than can be considered here.[1–10]

1.2 Practical Considerations

The success or failure of any biomolecular NMR project is completely dependent upon the quality of spectra generated by the particular samples under study. For

example, although it is generally true that proteins with $M_r > 50$ kDa are largely intractable projects by liquid-state NMR, there are examples of proteins with $M_r < 10$ kDa that give impossibly broad spectra, and proteins with $M_r > 60$ kDa that, with appropriate measures, give reasonably well-resolved spectra. Thus no NMR project should be ruled in or out without extensive preliminary tests of conditions to investigate whether the project is viable. In this sense, biomolecular NMR spectroscopy is similar to X-ray crystallography, where obtaining crystals is equivalent to getting a spectrum, and getting diffraction-quality crystals is equivalent to getting well-resolved spectra. Just as the X-ray crystallographer searches a wide variety of crystallization conditions, including testing temperature, pH, ionic strength, solvent and so on, so the NMR spectroscopist must carry out similar kinds of studies.

1.3 Instrumentation

For most biomolecular NMR studies, a high-field NMR spectrometer is necessary, at least 500 MHz (for ^{1}H, 11.7 T) for liquids and 400 MHz (9.4 T) wide-bore (89 mm) for solids – bigger is generally better (although there are reasons for doing studies at particular field strengths, as discussed later). For a biomolecular liquid-state NMR structure determination, generally a 600 MHz (14 T) instrument is preferable, whereas for biomolecular solid-state NMR structure determination (although there are advantages in going to higher fields) there are also technical issues that presently limit the kinds of experiments possible. The highest commercially available field strength (in early 1999) is 800 MHz (18.8 T), although a 900 MHz (21.2 T) instrument is scheduled for completion by summer 2000. To date, 800 MHz has become the field strength of choice in leading protein NMR laboratories doing liquid-state NMR, and a number of solid-state NMR laboratories are also exploring this field strength in their work.

2 BIOMOLECULAR SPECTRAL ASSIGNMENTS

The first step in biomolecular NMR spectroscopy, in particular by ^{1}H liquid-state NMR, is the assignment of the NMR spectrum. For this, a general strategy for identification and assignment of resonances is usually adopted, which employs a number of two-dimensional (2D) or higher (3D, four-dimensional (4D)) NMR experiments. Some of the basic experiments are discussed here, followed by an account of how they are employed in carrying out sequence-specific assignments. For large biomolecules these approaches fail and alternative methods are considered in section 2.3.3 for such situations. Once the assignments have been obtained, then this information can be used to solve the biomolecular structure (section 3) or used to interpret biochemical events (section 5.2).

2.1 Two-dimensional Nuclear Magnetic Resonance Experiments

2.1.1 Correlation Spectroscopy

The most important 2D NMR experiment is the correlation spectroscopy or COSY experiment, introduced by Jeener in 1971. The sequence consists of $90^\circ - t_1 - 90^\circ$ and, in the presence of homonuclear scalar J coupling, it gives information about coupling networks. In a coupled system, the second pulse of the experiment causes magnetization that arose from one transition during t_1 to be redistributed amongst all the others with which it is associated. With this sequence of pulses, in the presence of coupling, magnetization evolves with different frequencies during the two time intervals because coherence is transferred between multiplets during the second pulse.

Another important variant on the basic COSY sequence is double-quantum-filtered correlation spectroscopy (i.e. DQFCOSY), in which an extra $\pi/2$ pulse is added immediately after the end of the COSY sequence (Equation 1):

$$\frac{\pi}{2}_{\phi} - t_1 - \frac{\pi}{2}_{\phi} - \Delta - \frac{\pi}{2}_{x} - t_2(\text{acquire}) \quad (1)$$

where Δ is a short phase switching delay, and multiple quantum coherences that existed before the third pulse are converted back to observable magnetization. With a suitable choice of phase cycling, signals that have arisen from different orders of multiple quantum coherence can be separated out. For instance, double quantum coherence is twice as sensitive to phase changes in its excitation sequence as is single quantum coherence. Therefore by shifting the phase ϕ of the first two pulses (in general, *all* pulses before the coherence is created) by 90°, the phase of the detected signal which came via double quantum coherence is inverted. Inverting the receiver phase (i.e. subtracting the 90° from the 0° experiment) then selects the component which passed through double quantum coherence. To select p-quantum coherence, the rule is to step the phases of the excitation pulses through the sequence $0, 180/p, \ldots (2p-1) \times 180/p$, alternating the receiver phase for each scan. The advantages are considerable improvement in spectral simplification. Singlets are largely eliminated in DQFCOSY. Furthermore the diagonal *and* the cross-peaks are in pure absorption

phase, improving the resolution. The disadvantage is that DQFCOSY is less sensitive by a factor of 2 than conventional COSY.

2.1.2 Total Correlation Spectroscopy

Total correlation spectroscopy (TOCSY) or its variant homonuclear Hartmann–Hahn (HOHAHA) spectroscopy is an experiment that relies on cross-polarization (CP) rather than coherence transfer, and whose pulse sequence is shown in Figure 1.

The spin-locking field causes cross-polarization, or an oscillatory exchange of spin-locked magnetization between two spins, provided that the effective local RF fields experienced by the two spins are identical. This causes the spins to become temporarily equivalent. The spin-lock sequences are termed "isotropic mixing" (with no effective field) or "Hartmann–Hahn mixing" (with an effective field, i.e. this is the HOHAHA experiment). Isotropic mixing leads to spectra with mixed phases (phase modulated), whereas in Hartmann–Hahn mixing, pure phases are obtained. For a simple two-spin system, complete exchange of magnetization occurs for contact times (or spin-lock mixing times) equal to $1/(2J)$, where J is the two-spin scalar coupling constant. For biological macromolecules, which involve large spin systems, there is no simple analytical solution, and in practice spectra are usually obtained with a variety of spin-lock mixing times.

2.1.3 Heteronuclear Single Quantum Coherence and Heteronuclear Multiple Quantum Coherence

One of the most important experiments in biomolecular NMR is the heteronuclear single quantum coherence (HSQC) correlation experiment, and its more general form, the heteronuclear multiple quantum coherence (HMQC)[11] experiment (sometimes referred to as the "forbidden echo" experiment).[12–14] These experiments exploit the intrinsically greater sensitivity of protons to indirectly detect a heteronucleus such as ^{13}C and ^{15}N. The basic HMQC pulse sequence is shown in Figure 2.

Figure 1 The TOCSY pulse sequence. (Adapted from ref. 8 with permission.)

Figure 2 The basic HMQC pulse sequence. The delay Δ is usually set to ~20% less than $1/4(J_{IS})$. (Adapted from ref. 8 with permission.)

In terms of product operators, a heteronuclear spin system IS is represented by Equation (2),

$$I_z \xrightarrow{\text{A}} -2I_xS_y \xrightarrow{t_1} -2I_xS_y \cos w_S t_1 \xrightarrow{\text{B}} -I_y \cos w_S t_1 \tag{2}$$

where A and B are operators representing the effect of the pulse sequence before and after the t_1 period, respectively, and the pulse phases are assumed to be $+x$. Equation (2) indicates that the proton signal (I_y) which is detected will be in-phase and amplitude modulated by w_S, giving rise to a single absorption line in the 2D spectrum. Considering a second coupled proton M, then the effect of the small homonuclear coupling J_{IM} during the short delays Δ can be neglected. During t_1, dephasing caused by J_{SM} coupling is refocused by the 180° pulse. However, the effect of any J_{IM} coupling is not refocused, because both coupled nuclei are influenced by the 180° pulse. Therefore the effect of the pulse sequence is given by Equation (3):

$$\begin{aligned} I_z \xrightarrow{\text{A}t_1\text{B}} & -I_y \cos \pi J_{IM} t_1 \cos w_S t_1 \\ & + 2I_xM_z \sin \pi J_{IM} t_1 \cos w_S t_1 \end{aligned} \tag{3}$$

The detected signal will consist of four multiplet components at $w_S \pm \pi J_{IM}$ and $w_I \pm \pi J_{IM}$, and will contain both in-phase absorptive (I_y) and antiphase dispersive ($2I_xM_z$) components.

The pulse sequence of the HSQC experiment is shown in Figure 3.

Figure 3 The HSQC pulse sequence. (Adapted from ref. 8 with permission.)

This is a variation on an experiment introduced by Bodenhausen and Ruben[15] and employs two insensitive nuclear enhancement by polarization transfer (INEPT)-type[16,17] transfers to transfer magnetization from the protons to the low-γ nucleus and back to the protons. The INEPT sequence transfers I_{spin} (e.g. ^{1}H) I_z magnetization into antiphase S-spin magnetization. Decoupling the I-spin during t_1 is accomplished by application of a 180° pulse at the midpoint of t_1. A subsequent INEPT transfer reconverts the transverse S magnetization into observable I magnetization. Equation (4) expresses this in terms of product operators:

$$I_z \xrightarrow{\text{INEPT}} -2I_zS_y \xrightarrow{t_1} -2I_zS_y \cos w_S t_1 \xrightarrow{\text{reverse INEPT}} -I_x \cos w_S t_1 \tag{4}$$

where for clarity only those terms that contribute to the final spectrum are retained, and the phase of the pulses are given that correspond to the first step in the phase cycle. Pure absorptive lineshapes are obtained. Furthermore the linewidth is narrower than with the HMQC experiment, because it is not affected by homonuclear or heteronuclear J couplings and determined by the average relaxation rates of S_x and I_zS_y. There are a number of advantages that HSQC has over HMQC, principally in terms of sensitivity.[18–20] It is for this reason that HSQC has emerged as the gold standard for determining the viability of a biomolecular NMR project. A ^{1}H–^{15}N HSQC is routinely obtained on a protein to establish whether a particular sample gives well-resolved and well-dispersed spectra.

2.1.4 Nuclear Overhauser Effect Spectroscopy

The 2D experiment that permits the detection of the nuclear Overhauser effect (NOE) is the NOESY (nuclear Overhauser effect spectroscopy) pulse sequence given in Equation (5):

$$\frac{\pi}{2}_{\phi} - t_1 - \frac{\pi}{2}_{\phi} - \tau_m - \frac{\pi}{2}_{\phi} - \text{Acquire}(t_2) \tag{5}$$

The first 90°_x pulse creates transverse xy magnetization, and the spins now precess during t_1 as in the COSY sequence. The second 90°_x pulse rotates components of the magnetization along the $-z$ axis. During the subsequent mixing period τ_m, z-magnetization components exchange under the influence of cross-relaxation. The transverse components are not required and are removed by phase cycling. The magnetization vectors therefore have a component in the z direction only after these procedures. Finally, a third 90°_x pulse regenerates observable magnetization. If this sequence is repeated for a larger value of t_1, the magnetization vectors would dephase further, and a smaller $-z$ component is thus created, which would pass through zero and become positive for increasing values of t_1. The changes are "read" by the final 90° pulse. The cross-peaks are generated from the magnetization transfer (cross-relaxation) between two spins.

Note that in any practical application, a variety of cross-peaks can be generated by mechanisms other than cross-relaxation, and these cause confusion in interpreting the data. In addition, chemical exchange cross-peaks occur (which can be valuable if chemical exchange is known to be taking place), but can be a source of undesirable confusion. Furthermore, in a weakly coupled system the cross-relaxation pathways arising from coherence transfer between J-coupled spins has to be considered. By analogy with the COSY pulse sequence, the system remains the same until after the second 90° pulse, when the density operator takes the form of Equation (6):

$$\begin{aligned}\sigma_3 = [&-I_z \cos w_I t_1 + I_x \sin w_I t_1 - S_z \cos w_S t_1 \\ &+ S_x \sin w_S t_1] \cos \pi J_{IS} t_1 - [-2I_xS_y \cos w_I t_1 + 2I_yS_x \\ &\times \cos w_S t_1 - 2I_zS_y \sin w_I t_1 + 2I_yS_z \sin w_S t_1] \sin \pi J_{IS} t_1\end{aligned} \tag{6}$$

The terms $2I_xS_y$ and $2I_yS_x$ consist of a superposition of double- and zero-quantum coherences, which can be shown by expanding σ_3 (Equation 7):

$$\begin{aligned}\sigma_3 = [&-I_z \cos w_I t_1 + I_x \sin w_I t_1 - S_z \cos w_S t_1 \\ &+ S_x \sin w_S t_1] \cos \pi J_{IS} t_1 + \tfrac{1}{2}[(2I_xS_y + 2I_yS_x)^{[1]} \\ &- (2I_yS_x + 2I_xS_y)^{[2]}] \cos w_I t_1 + \tfrac{1}{2}[(2I_xS_y + 2I_yS_x)^{[3]} \\ &+ (2I_yS_x + 2I_xS_y)^{[4]}] \cos w_S t_1 + 2I_zS_y \sin w_I t_1 \\ &+ 2I_yS_z \sin w_S t_1 \quad \sin \pi J_{IS} t_1\end{aligned} \tag{7}$$

where the terms labeled [1] and [3] represent double quantum coherence, and those labeled [2] and [4] represent zero quantum coherence. As we are only interested in longitudinal magnetization components during the mixing period τ_m, it is necessary to remove all the components except $-I_z \cos w_I t_1$ and $-S_z \cos w_S t_1$. In order to do this, we can phase cycle the first two pulses by 90° each: xx, yy, $-x$, $-x$, $-y$, and $-y$, and add each separate response, then this will cancel coherences of order 1, 2, 3, 5, ... and leave the zero quantum coherences. Thus at the beginning of the mixing period Equation (8) holds:

$$\begin{aligned}\sigma_3 = &(-I_z \cos w_I t_1 - S_z \cos w_S t_1) \cos \pi J_{IS} t_1 \\ &+ (I_yS_x - I_xS_y)[\cos w_S t_1 - \cos w_I t_1] \sin \pi J_{IS} t_1\end{aligned} \tag{8}$$

The zero quantum term $(I_yS_x - I_xS_y)$ evolves in a way that depends on the difference in the chemical shifts, and the longitudinal $(-I_z)$ terms mix under the effects of cross-relaxation. After the final 90°_x pulse, the observable magnetization is given by Equation (9):

$$\begin{aligned}\sigma_4^{\text{obs}} = [&I_y a_{II}\cos w_I t_1 + S_y a_{SS}\cos w_S t_1 + I_y a_{SI}\cos w_S t_1 \\ &+ S_y a_{IS}\cos w_I t_1]\cos \pi J_{IS} t_1 + (I_z S_x - I_x S_z) \\ &\times \cos(w_I - w_S)\tau_{\text{m}}(\cos w_S t_1 - \cos w_I t_1)\sin \pi J_{IS} t_1\end{aligned} \tag{9}$$

The terms in σ_4 represent diagonal peaks proportional to the mixing coefficients a_{II} and a_{SS}, and NOE cross-peaks proportional to a_{SI} and a_{IS}. These are all in phase with respect to J_{IS}. Also, there are diagonal and cross-peaks that are antiphase with respect to J_{IS}. These are the J cross-peaks derived from zero quantum coherence that cannot be removed by phase cycling, and have to be eliminated by other methods (e.g. random incremental variation of τ_{m}).

For a three-spin system, I, S, and M, the I-spin diagonal peak intensity governed by a_{II} decays with increasing τ_{m}, whereas the S- and M-spin cross-peak intensities, generated by a_{IS} and a_{IM}, increase before decaying with increasing τ_{m}. The importance of the time development of cross-peak intensities is that the initial build-up rates of the S- and M-spin cross-peaks (i.e. at $\tau_{\text{m}} = 0$) are proportional to σ_{IS} and σ_{IM}. If, therefore, a_{IM} corresponds to a known fixed internuclear distance r_{IM}, r_{IS} can be calculated from the r^{-6} dependence of σ (Equation 10):

$$\frac{r_{IM}}{r_{IS}} = \left(\frac{\sigma_{IS}}{\sigma_{IM}}\right)^{\frac{1}{6}} \tag{10}$$

This is the principal method by which quantitative distance information is obtained in biomolecular NMR. A series of NOESY spectra is recorded as a function of mixing time in order to generate experimental plots similar to those obtained experimentally, as shown above. Alternatively, if one can be certain that the measured cross-peak intensities in a single NOESY experiment for a given mixing time were developed within the initial rate approximation, then quantitative distance information can be obtained with good accuracy by measurement of relative cross-peak intensities rather than initial rates (Equation 11):

$$\frac{r_{IM}}{r_{IS}} = \left(\frac{a_{IS}}{a_{IM}}\right)^{\frac{1}{6}} \tag{11}$$

Note that this is true for the initial rate approximation only.

2.2 Three-dimensional and Four-dimensional Experiments

One of the problems with ^{1}H NOESY NMR of proteins is that all the NOEs must be resolved. This becomes increasingly difficult with higher-molecular-weight proteins. To solve this problem, a whole family of pulse sequences have been introduced that involve three time variables rather than two, so that 3D Fourier transformation leads to a cube rather than a contour map. They involve using an isotopic label for indirect detection via HMQC/HSQC methods in combination with a type of COSY or NOESY sequence. Almost all of these 3D (and 4D) pulse sequences rely on heteronuclear and homonuclear couplings for correlating resonances from

Figure 4 A dipeptide segment of a protein backbone with typical values of homonuclear and heteronuclear J couplings, and showing the correlations obtained using the selection of experiments indicated. Nuclei for which the chemical shift is measured in the 3D (or 4D) experiment are marked by dark shaded circles. Nuclei involved in the magnetization transfer pathway, but not observed, are marked by light shaded circles. Magnetization transfer is marked by curved solid lines, and the direction of the transfer indicated with arrows. Note that sequences involving small J couplings are generally not suitable for large proteins and are usually less sensitive. (Adapted from ref. 8 with permission.)

one residue to the next, in for example an oligopeptide, oligonucleotide or oligosaccharide. Rather than provide a detailed description of all the pulse sequences used in modern biomolecular NMR, they are summarized in Figure 4. The *J* couplings involved, and the correlations which each sequence can obtain, are illustrated in Figure 5 for a dipeptide fragment.

The majority of experiments involve a heteronucleus, and coherence is transferred from one nucleus to the next, usually ending up on ^{1}H, which is then detected. Such coherence transfers are achieved using INEPT and related approaches. As is clear from Figure 5, the amide protons are correlated with the α carbons using the HNCA[21–25] and HN(CO)CA[25,26] experiments. The HNCA provides intraresidue correlations (H_i^N N_i^H $C_i^\alpha\{C_{i-1}^\alpha\}$), whereas the HN(CO)CA provides exclusively interresidue correlations (H_i^N N_i^H C_{i-1}^α). The latter experiment is more sensitive and is complementary to the HNCA experiment. The amide protons are correlated with the α protons using the H(CA)NNH, HN(CA)H, HN(CA)HA, and HN(COCA)HA experiments. The H(CA)NNH,[27,28] HN(CA)H,[29] and HN(CA)HA[30] experiments all provide the same correlations (H_i^N N_i^H $H_i^\alpha\{H_{i-1}^\alpha\}$). The HN(CA)NNH situation is not very sensitive for $M_r >$ 20 kDa, and HN(CA)HA is significantly more sensitive and has been used to assign a 27-kDa protein.[31] The HN(CA)H has even more improved sensitivity, particularly for larger proteins (>30 kDa). The HN(COCA)HA[32] correlates H_i^N N_i^H H_{i-1}^α, and is analogous to the HN(CO)CA, providing exclusively interresidue correlations, and is therefore complementary

Figure 5 Some examples of 3D and 4D pulse sequences. These are presented in their simplest form, without pulse field gradients or constant-time implementations. (Adapted from ref. 8 with permission.)

to the H(CA)NNH, HN(CA)H, and HN(CA)HA experiments. The amide protons are correlated with the carbonyl carbons using the HNCO and HN(CA)CO experiments. The HNCO[21,22,33,34] experiment correlates H_i^N N_i^H C'_{i-1}, and its high sensitivity makes it attractive in assignment strategies. The HN(CA)CO[25,35] provides intraresidue and some weaker interresidue correlations, but is much less sensitive, and therefore complementary to the HNCO experiment. The amide protons are correlated with the α and β protons using the CBCA(CO)NH, CBCANH, HNCACB, HBHA(CBCACO)NH, and HBHA(CBCA) NH experiments. The CBCA(CO)NH[33,36] experiment correlates H_i^N N_i^H $C_{i-1}^{\alpha,\beta}$, and is an extension of the HN(CO)CA experiment, as it correlates both the C^β and C^α chemical shifts with the amide from the previous residue. The CBCANH[37] experiment correlates H_i^N N_i^H $C_i^{\alpha,\beta}\{C_{i-1}^{\alpha,\beta}\}$, and is an extension of the HNCA experiment, providing mainly intraresidue correlations, but with some interresidue correlations. Although in principle this one experiment can provide complete assignments for C^β, C^α, ^{15}N, and H^N resonances, like the HNCA experiment, the sensitivity is limited, and it is mainly useful for smaller proteins ($M_r < 20$ kDa). The HNCACB[33,38] experiment provides the same information as the CBCANH, but is more sensitive. By using these experiments in conjunction with the HBHA(CBCACO)NH[39] (H_i^N N_i^H $H_{i-1}^{\alpha,\beta}$) and the HBHA(CBCA)NH[40] (H_i^N N_i^H $H_i^{\alpha,\beta}\{H_{i-1}^{\alpha,\beta}\}$) experiments, the assignment can be extended to the carbon-attached protons as well. In all these experiments, both the α and β correlations appear in the same dimension.

The HCACO[21,22,41–43] experiment (H_i^α C_i^α C'_i) and the HCA(CO)N[21,22,41] experiment (H_{i-1}^α C_{i-1}^α N_i^H) are both usually acquired with a sample in D_2O, in order to allow observation of those α protons otherwise obscured by the water resonance. This has the disadvantage of requiring two different samples in which small differences in preparation conditions can lead to differences in chemical shifts, and the presence of the deuterium leads to isotope shifts. However, the HCACO is more sensitive than other experiments such as the HN(CA)HA. Also, the HCA(CO)N is useful for identifying residues preceding proline residues. There are also several other 3D sequences that have been proposed, such as the HN(CA)NNH[44] (H_i^N N_i^H N_{i+1}^H), H(NCA)NNH[44] (H_i^N N_i^H N_{i+1}^H), H(N)CACO[45] (H_i^N C_i^α C'_i), and HA[CAN]HN[46] ($H_i^N[N_i^H + C_i^\alpha]$ H_i^α). These have not been as widely used in protein assignment strategies. Finally there is also the HCACOCANH (H_i^N N_i^H C'_i) experiment,[47] which appears to be gaining in popularity.

The most common experiments for side-chain assignment are the HCCH COSY[48] and the HCCH TOCSY.[49–51] These provide essentially the same information (H_i^x C_i^x H_i^y with C^x and C^y being one bond apart) as the 2D COSY/TOCSY experiments, except that the COSY/TOCSY transfer is between carbon rather than proton nuclei. The third dimension correlates the shifts of the ^{13}C nuclei attached to the protons on the diagonal which reduces the overlap. However, one disadvantage is that they are generally acquired with the sample dissolved in D_2O. One way round this is the HNCCH TOCSY[52] experiment, which correlates the amide nitrogens, the α carbons, and the side-chain protons on a sample in H_2O. Alternatively, there are the C(CO)NH (H_i^N N_i^H $C_{i-1}^{x,y,z,\cdots}$) and H(CCO)NH (H_i^N N_i^H $H_{i-1}^{x,y,z,\cdots}$) experiments,[53] which are both more sensitive.

There are a number of 4D experiments, although they all suffer from poor sensitivity. It is a necessity that 4D experiments use pulsed field gradients for coherence selection [54–56] with a minimum of phase cycling. They have been used as the only source of backbone assignments.[57] The HCANNH (H_i^N N_i^H $H_i^\alpha\{C_{i-1}^\alpha$ $H_{i-1}^\alpha\}$) and HCA(CO)NNH (H_i^N N_i^H H_i^α C_{i-1}^α H_{i-1}^α) experiments[58] are complementary, and can provide complete sequential assignments for all the backbone atoms apart from the carbonyl carbons. The HCANNH experiment gives intraresidue correlations and a few interresidue correlations; the HCA(CO)NNH gives exclusively interresidue correlations. Improved constant-time versions have also been introduced.[59] The HNCAHA and HN(CO)CAHA experiments[60,61] together provide the correlations, but use different pulse sequences. In general the HCANNH is preferable for small proteins, whereas the HNCAHA is more sensitive for proteins with $M_r > 20$ kDa. The HCC(CO)NNH[62] experiment (H_i^N N_i^H $C_{i-1}^{x,y,z,\cdots}$ $H_{i-1}^{x,y,z,\cdots}$) is based on the HCA(CO)NNH and allows the assignment of the side-chain as well as the α nuclei.

The use of these experiments in carrying out sequential assignments is outlined in the next section.

2.3 Sequence-specific Assignments

2.3.1 Sequential Assignments for Proteins with Relative Molecular Mass below 15 kDa

The standard notation used for distances in proteins is that the distance between the hydrogen atoms A and B located in the amino acid residues in the sequence positions i and j, respectively, is denoted by $d_{AB}(i, j)$. This notation can be applied to all hydrogen atoms, but in practice the distances between different backbone hydrogen atoms and between backbone hydrogens and βCH_n groups are of particular interest. The standard approach for the sequential assignments of a small ($M_r < 15$ kDa) protein is to carry out the following four steps:

1. The spin systems of nonlabile protons in individual amino acids are identified for the native protein in D_2O by DQFCOSY and TOCSY experiments.
2. From studies in H_2O, the identity of amino acid spin systems of the individual residues are completed through identification of the J connectivities with the labile protons.
3. Sequentially neighboring amino acid ^1H spin systems are identified from observation of the sequential NOE connectivities $d_{\alpha N}$ or d_{NN}, or possibly $d_{\beta N}$.
4. The aim of steps 1–3 is to identify groups of ^1H-NMR lines corresponding to peptide segments that are sufficiently long to be unique in the primary sequence, or a single residue which is unique. Sequential assignments are then obtained by matching the peptide segments thus identified by NMR with the corresponding segments in the independently determined (not by NMR) amino acid sequence.

For unique residues, the sequential assignment follows directly from the identification of the spin system. For the resonances of unique dipeptide segments, sequential assignments result if a sequential connectivity between the ^1H spin systems of the two residues can be established. The unique residues and dipeptide segments can then be used as reference locations in the primary structure, so that further sequential identification steps directly provide the sequential assignments for the adjacent residues. The characteristic chemical shifts for random extended chain structures (sometimes inappropriately called random coil) are available.[8] Also the amino acid residues display characteristic cross-peak fine structures in their DQFCOSY spectra. Using this type of information, generally all but the side chains of Lys and Arg beyond the βCH_2 can be readily identified for proteins with $M_r \leq 15\,000$. Other techniques (e.g. TOCSY) are needed for the complete assignment of all the resonances for Lys and Arg.

The NOEs characteristic of short distances can be identified by comparing NOESY and COSY spectra. Common NOEs correspond to the sequential distances for the i to the $i+1$ residues. The importance of observing the NH signals in H_2O is clear. Finally, comparison of the α helix and β sheet distances shows that a regular secondary structure can be spotted and categorized by its NOE pattern. α-Helices have particularly short sequential d_{NN} values, and β sheets have short $d_{\alpha N}$ values. Even more characteristic are the short $d_{\alpha N}(i, i+3)$ and $d_{\beta N}(i, i+3)$ distances found in helices, and the short interstrand $d_{\alpha N}(i, j)$, $d_{NN}(i, j)$ and $d_{\alpha\alpha}(i, j)$ distances found in β sheets. Indeed, even without any sequential assignments, the presence of $d_{\alpha\alpha}$ NOEs can be used as a crude diagnosis for antiparallel β sheets.

2.3.2 *Sequential Assignments for Proteins with Relative Molecular Mass in the Range 15–50 kDa*

For larger proteins the problem of overlapping resonances and increased linewidths can become severe, and the solution is to turn to isotopic labeling and 3D heteronuclear NMR. This is because the heteronuclear couplings, $^1J_{CH}$ (125–160 Hz) and $^1J_{NH}$ (≈92 Hz), are much larger than $^3J_{HH}$, and frequently as much as 50–90% of the magnetization can be transferred from protons to their directly coupled heteronuclei.[63] Consequently, such heteronuclear shift correlation experiments are highly sensitive. The strategy for making 3D heteronuclear NMR assignments relies exclusively on homonuclear and heteronuclear J coupling, which avoids the use of NOE connectivities, and makes use of several different experiments illustrated in Figure 5. The strategy was introduced originally by Markley et al.[64,65] The advantage of avoiding NOE-based strategies for the assignment of larger protein spectra is that it is largely independent of protein conformation, and relies only on one-bond coupling. However, each sequential connectivity depends upon a single correlation. Degeneracy of carbon and nitrogen resonances can be more hampering than degeneracy of proton resonances in the case of the NOE-based assignments, where observation of more than one of the $d_{\alpha N}$, d_{NN} and $d_{\beta N}$ connectivities can resolve ambiguities. Therefore, these heteronuclear strategies can also be combined with homonuclear NOESY experiments, although the presence of isotopic labeling, for example with ^{13}C, can exacerbate the linewidth problem for large proteins because the $^1H-^{13}C$ dipolar interaction causes additional proton line broadening.

Typical values for the relevant coupling constants are indicated in Figure 5. Equally important are the magnitudes of the t_2 relaxation times, which determine the linewidth and depend approximately linearly on the rotational correlation time, and on the degree of internal mobility and local conformation. Generally, for residues that do not have a high degree of internal mobility in a globular protein of $M_r \approx 20$ kDa at 35 °C, the linewidths are about 12 Hz for the NH proton, for ^{15}NH nitrogen ≈7 Hz (^1H coupled) and ≈4 Hz (^1H decoupled), ≈15 Hz for $^{13}C^{\alpha}$, and ≈25 Hz for a ^{13}C-attached $^1H^{\alpha}$. The linewidth of the carbonyl is dominated by chemical shift anisotropy and therefore is proportional to the square of $\mathbf{B}_0$, and ≈6 Hz at 11.7 T. Comparison of these values with those shown in Figure 5 indicate that for a 20 kDa protein most one-bond J couplings are significantly larger than the linewidths, which means that magnetization can be transferred efficiently from one spin to its directly attached coupling partner. Use of a combination of these experiments permits the complete sequential assignments for proteins up to a maximum

$M_r \approx 50$ kDa. For proteins with favorable resonance dispersion and sensitivity, the HNCA, HCACO, and HN(CA)CO experiments may not be necessary to complete the assignments.[66]

Common assignment strategies for heteronuclear triple resonance experiments often start with correlating $^1H/^{15}N$ shift pairs for backbone amides (from HSQC or, if too overlapped, HNCO experiments) with other nuclei via the HNCA experiment. Although other correlations can in principle be achieved using a HN(CO)CA experiment, in practice a combination of other experiments are usually carried out. For example, the HNCA, TOCSY/HMQC, NOESY/HMQC, HBHA(CO)NH, CBCA(CO)NH, and CBCANH together give correlations between the $^1H/^{15}N$ amide resonances and the intraresidue/sequential C^α, C^β, H^α, and H^β shifts. However, using the C^α and C^β shifts and the results from a C(CO)NH experiment, the amino acid type can be determined for each $^1H/^{15}N$ pair. This can be confirmed using the 4D HN(COCA)NH experiment.[67] For larger proteins, a typical strategy would be to use HNCA, HN(CO)CA, and HNCO experiments to correlate the NH_i pairs to the C_i^α, $\{C_{i-1}^\alpha\}$, and C'_{i-1} shifts with high sensitivity. The HN(CA)CO experiment can provide intraresidue C'_i correlations, and TOCSY/HMQC can provide H_i^α correlations, although with lower sensitivity. The HCACO can be used to correlate the H_i^α, C_i^α, and C'_i shifts for all residues other than glycine. The assignments obtained by this means can then be checked against the HN(CA)HA, HA(CACO)NH, and the side-chain resonances of the TOCSY/HMQC experiment. The glycine resonances can be checked against an appropriately optimized (for CH and CH_2 groups) HCACO experiment. The α-carbon shifts of glycine can generally be found from the HCCH COSY and correlated with NOESY/TOCSY/HMQC. These strategies can always break down at any point, and alternative experiments can be employed to fill in the gaps.

The key to carrying out multidimensional NMR studies on proteins with $M_r < 50$ kDa, and structural investigations on selected regions of proteins with $M_r > 50$ kDa, involves the use of isotopic labeling. This can be either universal labeling or selective labeling. The isotopes commonly employed under these circumstances are ^2H, ^{13}C, and ^{15}N. For isotopic labeling to be practical, it is essential that the protein of interest is overexpressed at a sufficiently high level in an organism that is easy to handle. Generally this means that the gene encoding a particular protein should be inserted into a plasmid with a good promoter, and most conveniently in a suitable strain of *Escherichia coli*. A reasonable target for levels of overexpression for ^{13}C,^{15}N double labeling should be in the region of 10–50 mg of purified protein from 1 L of cells. Lower levels of overexpression can be tolerated for universal labeling with ^{15}N, as $^{15}NH_4Cl$ is relatively cheap.

Deuterium labeling can be used to simplify ^1H-NMR spectra of proteins.[68,69] The modern approach has focused on reducing the $^1H-^1H$ dipolar interaction through fractional deuterium labeling.[70–72] There are a number of advantages to the use of deuteration for NMR studies of larger proteins. Random deuteration helps to reduce spin diffusion, and incorporation of stereospecifically deuterated amino acids helps to resolve degenerate proton resonances and enable quantitative NOE analysis. Chiral deuteration can aid in stereospecific assignments, but is rarely employed because it is experimentally difficult.

2.3.3 Methods for Extending the Molecular Weight Limit

There are a number of approaches for extending the molecular weight limit that NMR imposes on the study of biomolecules. At the root of the problem is the fact that larger molecular weight particles tumble more slowly, generally leading to longer correlation times (τ_c), which in turn leads to broader lines. Therefore approaches that narrow these broad lines are what is required. One rather obvious approach is to stop the molecular tumbling by going to the solid state, and then to employ the methods of solid-state NMR such as cross-polarization/magic-angle spinning (CP/MAS) to narrow the lines. These techniques throw away important information, such as the dipolar coupling, so techniques to reintroduce these couplings are necessary (section 4) for solid-state NMR to be useful in structural biology. In solution, a number of approaches have been introduced which can be used separately or in concert. Use of deuterium labeling, as discussed in the previous section, helps to reduce linewidths substantially. Also Hahn spin–echo sequences can be used to edit with respect to broad lines in the presence of narrow lines. Recently a new approach called transverse relaxation optimized spectroscopy (TROSY) has been introduced[73] which relies on the cancellation of two competing effects at high magnetic field strength. These effects are the dipolar relaxation and chemical shift anisotropic relaxation. Some TROSY variants on the complete set of standard 3D protein NMR pulse sequences have been introduced.[74,75] It has been suggested[73] that these approaches will be applicable to proteins up to 500 kDa. In practice the benefits depend on the system under study, and in some situations TROSY versions of 3D experiments are preferable for large proteins even at low field strengths (500–600 MHz ^1H), and in some cases the significant loss of sensitivity with TROSY is too high a price to pay.

3 BIOMOLECULAR STRUCTURE DETERMINATION

The application of NMR spectroscopy both in solution and in the solid state can generate a variety of distance and angle restraints that can be used in computing the 3D structure of a biomolecule. These restraints can only be interpreted once the spectral assignments have been made, and may be obtained in a number of ways. The accuracy of distance and angle measurements depends largely on the technique, with those methods that yield the lowest number of restraints tending to give more accurate data, although in the case of solid-state NMR data this usually defines the local rather than the global structure. However, accuracy is not always required in order to determine a structure with high precision. Protein structures can be obtained with high precision with relatively poorly defined distance restraints, such as those obtained from NOESY experiments. However, the same does not hold for DNA, for which accurate distances are required. Furthermore, the use of NOEs is generally confined to those molecules whose molecular weight is above 50 000 (or whose overall rotational correlation time τ_c is long). For larger molecules alternative strategies have to be employed, which include solid-state NMR techniques, residual dipolar coupling measurements, and TROSY approaches (sections 2.3.3 and 4.2).

3.1 Assigning Nuclear Overhauser Effect Intensities

Nuclear Overhauser enhancements can be used to obtain distances between protons up to about 5 Å apart. In general, NOESY spectra are obtained at a variety of mixing times, τ_m. This enables the region where the NOE build-up rates are linear to be determined. Note that at long mixing times or for large biomolecules ($M_r > 50\,000$), spin diffusion takes place, in which cross-relaxation is propagated across the molecule from one nucleus to another. This can be avoided by ensuring that the initial rate condition is fulfilled. The cross-peak intensities in NOESY spectra can be measured to an accuracy of about 10%. As the NOE build-up rate depends on r^{-6}, where r is the distance between the two protons, it might be hoped that distances can be obtained very accurately. However, local internal motion, together with other contributory forms of relaxation or exchange, are the reasons why high accuracy is not obtainable in practice.

Thus, in general NOESY cross-peak intensities are classified into four different categories, with distances of 1.8–2.7 Å, 1.8–3.3 Å, 1.8–5.0 Å, and 1.8–6.0 Å for strong, medium, weak, and very weak NOEs. Although this classification is somewhat arbitrary, it works well in practice. Usually the NOE cross-peak intensities are calibrated against some internal standard fixed length, and the choice of such a standard is important because local motion can lead to erroneous results. For example, calibration using the δ and ε protons of an aromatic ring is quite common, and yet it is not uncommon for aromatic side chains (at least in proteins) to give NOEs which vary too much to be reliable. Care has to be taken to ensure that there is relative molecular motion in the functional group being used for distance calibration. Strong NOEs usually appear as intense cross-peaks in NOESY spectra even at short mixing times (e.g. $\tau_m = 50$ ms for a protein whose M_r is below 20 000). In the same spectra, medium NOEs appear as weak cross-peaks. The weak NOEs appear only at longer mixing times (e.g. $\tau_m = 200$ ms for a protein whose M_r is below 20 000) and may be due to indirect effects. The lower bound is kept the same for each category because local motion could severely attenuate the NOE, even for short distances. These distance bounds or restraints are used as input into computer algorithms for the calculation of the 3D structure (sections 3.3 and 3.4). Even though only ranges of distances for a given pair of atoms can be found, these restrict drastically the number of possible structures, and refinement protocols (section 3.6) ensure that a low-energy structure can be determined.

3.2 Use of *J* Couplings to Obtain Torsion Angles

Judicious use of the Karplus relation ($J = A + B\cos\theta + C\cos^2\theta$) yields information on the dihedral angles.[76,77] The constants in the Karplus relationship have been determined empirically. In proteins, the couplings of interest are the three-bond couplings; in particular $^3J_{H\alpha,NH}$ is related to the angle ϕ, and $^3J_{H\alpha,H\beta}$ and $^3J_{N,H\beta}$ are related to χ_1. These relationships have been calibrated on known structures[78,79] and are given in Equation (12) (in Hertz):

$$\begin{aligned}
^3J_{H\alpha,HN}(\phi) &= 6.4\cos^2(\phi - 60^\circ) \\
&\quad - 1.4\cos(\phi - 60^\circ) + 1.9 \\
^3J_{H\alpha,H\beta2}(\chi_1) &= 9.5\cos^2(\chi_1 - 120^\circ) \\
&\quad - 1.6\cos(\chi_1 - 120^\circ) + 1.8 \\
^3J_{H\alpha,H\beta3}(\chi_1) &= 9.5\cos^2\chi_1 - 1.6\cos\chi_1 + 1.8 \\
^3J_{N,H\beta2}(\chi_1) &= -4.5\cos^2(\chi_1 + 120^\circ) \\
&\quad + 1.2\cos(\chi_1 + 120^\circ) + 0.1 \\
^3J_{N,H\beta3}(\chi_1) &= -4.5\cos^2(\chi_1 - 120^\circ) \\
&\quad + 1.2\cos(\chi_1 - 120^\circ) + 0.1
\end{aligned} \tag{12}$$

Using these equations, the dihedral angles ϕ and χ_1 may be calculated from both homonuclear and heteronuclear couplings.[80] There are corresponding important dihedral

angles in other types of biomolecules, such as in DNA and carbohydrates.

Accurate measurement of J couplings in an overlapping one-dimensional spectrum of a biomolecule can be very difficult. Two-bond and three-bond coupling constants may be extracted with care from the antiphase multiplet structure of the cross-peaks in phase-sensitive COSY or DQFCOSY. A better approach is to use one of a number of modified COSY experiments which simplify the cross-peak multiplet structure, such as ECOSY[81] (exclusive correlation spectroscopy), or PECOSY[82] (primitive exclusive correlation spectroscopy). The disadvantage of the ECOSY experiment is that it has very low sensitivity. The PECOSY experiment is at least four times more sensitive than the ECOSY experiment.

For larger biomolecules, measurement of J couplings from the PECOSY spectrum is difficult because of extensive resonance overlap. In these cases, an estimate of the values for J couplings may be obtained with ^{15}N-labeled material, from the cross-peaks in a 3D ^{1}H–^{15}N TOCSY/HMQC spectrum. The extent of magnetization transfer during the Hartmann–Hahn spin-lock depends on the magnitude of the scalar J coupling.

The measured coupling constant represents the time average (on the 100-ms timescale) of the actual J coupling. Thus the interpretation of a measured J coupling can be hampered by uncertainty as to whether it represents a J value that corresponds to a single dihedral angle, or whether it represents a rapid averaging of J values from quite different dihedral angles. When a biological molecule does not exist as a single conformation, but as an equilibrium of rapidly interconverting conformers, the NOE and J contain time-averaged distance and angle information. Both averaging processes are strongly nonlinear in their dependence on geometry, and the presence of multiple conformations can lead to NOEs and J couplings that cannot simultaneously be consistent with a single conformation.

The stereospecific assignment of resonances in a biomolecule, for example the β-methylene protons or methyl resonances of leucine or valine, can be extremely important in defining local conformations. Early NMR structures were obtained by treating NOEs involving chiral protons with indistinguishable chemical shifts ($<$0.01 ppm) as a single distance to the geometric center between the two methylene protons, with a 1 Å correction added to the upper bound of the measured distance to correct for the difference in position of the so-called pseudo-atom relative to the true proton. Similarly the distance to the geometric center of a methyl group was used with a corresponding increase of 2.4 Å to the upper bound for the measured distance. Instead of using pseudo-atoms, a more rigorous approach is to match the experimental NOEs and J coupling constants with those calculated for conformations present in a database. Both possible stereospecific assignments are considered, and if the database contains only conformations consistent with one of the two possibilities, then the correct assignment, together with the allowed ranges for ϕ, ψ, and χ_1, can be determined. In practice only about 50% of the possible stereospecific assignments can be made in an unambiguous manner.

The $^{3}J_{\mathrm{HN}\alpha}$ can be used in crude calculations to provide ϕ backbone torsion-angle restraints, which for proteins can be classified into two ranges: $^{3}J_{\mathrm{HN}\alpha} < 6$ Hz corresponding to $-35^\circ < \phi < -85^\circ$; and $^{3}J_{\mathrm{HN}\alpha} > 8$ Hz corresponding to $-80^\circ < \phi < -175^\circ$. Refinement of these numbers using the methods already outlined, including more accurate ϕ, ψ, and χ_1 torsion angles and stereospecific assignments, can almost double the number of experimental restraints that are used as input to distance geometry and related algorithms. As a general rule of thumb, helices exhibit $^{3}J_{\mathrm{NH}\alpha} < 6$ Hz, β-sheets exhibit $^{3}J_{\mathrm{NH}\alpha} > 8$ Hz, and random extended chains exhibits $^{3}J_{\mathrm{NH}\alpha} = 6$–8 Hz. Note, however, that deviations from this rule occur when proline is present.

3.3 Distance Geometry

Distance geometry[83–85] involves taking the restraints together with the covalent structure, and creating a matrix of interatomic distances between all atoms so as to be consistent with the input. This approach is called the metric matrix distance geometry and the set of distances from n-dimensional space are projected into 3D Cartesian coordinate space. This method operates in distance space, whereas there are also real space methods which operate in either Cartesian coordinate space directly, or in torsion-angle space.[86] The algorithm involves no initial priming with any kind of initial approximate structure. Indeed most versions start from a set of randomly generated structures with the restraints embedded. It is therefore a very unbiased way of determining structure. Mathematically, the metric matrix distance geometry approach calculates a selection of trial distances to replace the upper and lower bounds in the distance matrix **D**. The trial distances d_{ij} are usually selected randomly although they must still satisfy the bounds (Equation 13):

$$l_{ij} \leq d_{ij} \leq u_{ij} \tag{13}$$

Next the distance is calculated from each point i to the center of mass, denoted as point 0, using Lagrange's theorem (Equation 14):

$$d_{i0}^2 = \frac{1}{N}\sum_{j=1}^{N} d_{ij}^2 - \frac{1}{N^2}\sum_{j=2}^{N}\sum_{k=1}^{j-1} d_{jk}^2 \tag{14}$$

The metric matrix g_{ij} is defined as the scalar product of the two vectors, $\vec{u}_i$ and $\vec{u}_j$, and can be easily calculated from the distances using the law of cosines (Equation 15):

$$g_{ij} \equiv \vec{u}_i \cdot \vec{u}_j = \tfrac{1}{2}(d_{i0}^2 + d_{j0}^2 - d_{ij}^2) \tag{15}$$

Calculating the metric with respect to the center of mass means that no coordinates are emphasized, and all the coordinates are comparable in magnitude. Repeating for all atom pairs yields the metric matrix **G**. The metric matrix can also be thought of as a matrix containing the projections of all atom pairs. The eigenvalues $\lambda_1, \lambda_2, \lambda_3, \ldots$ are determined and ranked according to magnitude. The three largest eigenvalues are selected and are by nature mutually orthogonal. The corresponding eigenvectors of the real symmetric metric matrix **G** compose an N-column matrix **W**, where N is called the embedding dimensionality and is usually three. The largest eigenvalues are chosen as the principal axes so as to minimize scatter into higher dimensions. Thus the embedded coordinates, v_{ij}, for point i in N dimensions, where $j = 1, 2, \ldots, N$ are given by Equation (16):

$$v_{ij} = \lambda_N^{\frac{1}{2}} w_{ij} \tag{16}$$

One difficulty with metric matrix distance geometry is that distances alone cannot define the chirality of the structure, so that mirror images (local or global) of the correct structure can occur. In general, these can easily be rejected at the substructure stage as the chirality of single amino acids (L) and helices (right-handed) is known. A further problem associated with the method is that it does not sample efficiently the conformational space consistent with the stereochemical and experimental restraints. As a result, the atomic root mean square (RMS) distribution of a series of calculated structures tends to be underestimated, particularly in regions that are poorly defined by the experimental data. Subjecting these structures to restrained molecular dynamics (RMD), for example, results in an increase in the atomic RMS distribution, while improving the agreement with the experimental data and reducing the van der Waals energy.

In methods involving minimization in torsion angle space, bond lengths and angles are kept fixed during the minimization and only the torsion angles are varied. To ensure that correct folding occurs, the restraints have to be introduced gradually during the calculation. This is achieved in a variety of ways, so that the distances between residues further and further apart in the sequence are incorporated in successive cycles of minimization. In general, the structures found by these methods tend to have inordinately high energies and have to be subjected to extensive energy minimization with only minimal changes in atomic RMS deviations.

3.4 Molecular Dynamics and Simulated Annealing

When restrained energy minimization methods are used, inevitable local energy minima are encountered which can lead to inaccurate structures. To circumvent this, RMD are usually employed. This involves including NMR restraints in one of the many molecular dynamics simulation programs. Molecular dynamics[87,88] solves Newton's equations of motion (Equation 17),

$$F_i = m_i a_i \tag{17}$$

where F_i is the force, m_i is the mass, and a_i is the acceleration of atom i. The force on atom i can be computed directly from the derivative of the potential energy V with respect to the coordinates r_i. The energy can be expressed in the explicitly differentiable form of Equation (18):

$$-\frac{\mathrm{d}V}{\mathrm{d}r_i} = m_i \frac{\mathrm{d}^2 r_i}{\mathrm{d}t_i^2} \tag{18}$$

Therefore, with an adequate expression for the potential energy and known masses, this differential equation can be solved for future positions in time, t_i. In general, this can be solved only approximately, as V is usually a complex function of the coordinates of all (or many) of the atoms (i.e. $V = V(r_1, r_2, r_3 \ldots r_N)$). The temperature can be calculated from the atomic velocities (Equation 19),

$$\frac{3N}{2} k_{\mathrm{B}} T = \sum_{i=1}^{N} \frac{1}{2} m_i v_i^2 \tag{19}$$

where k_{B} is Boltzmann's constant, m_i and v_i are the mass and velocity of atom i, and N is the number of atoms (and $3N$ is the number of degrees of freedom). For a simulation at constant energy, the temperature fluctuates due to the interconversion of kinetic and potential energy. If the temperature is held constant, then the atomic velocities can be adjusted accordingly. If the pressure is held constant, the volume must be allowed to fluctuate by rescaling the interatomic distances.The total potential energy, V_{total}, is usually defined (Equation 20) as the sum of a number of terms:

$$V_{\mathrm{total}} = V_{\mathrm{bond}} + V_{\mathrm{angle}} + V_{\mathrm{dihedr}} + V_{vdW} + V_{\mathrm{coulomb}} + V_{\mathrm{NMR}} \tag{20}$$

where V_{bond}, V_{angle}, and V_{dihedr} keep bond lengths, angles and dihedral angles at their equilibrium values. (The first five terms are empirical energy terms describing the physical interactions between the atoms, whereas the last term is a means of including the NMR information, but does not correspond to any real physical force.) They are

summarized in Equations (21–23):

$$V_{\text{bond}} = \sum_{\text{bonds}} \frac{1}{2} K_b (b - b_0)^2 \tag{21}$$

$$V_{\text{angle}} = \sum_{\text{angles}} \frac{1}{2} K_\theta (\theta - \theta_0)^2 \tag{22}$$

$$V_{\text{dihedr}} = \sum_{\text{dihedr}} K_\phi [1 + \cos(n\phi - \delta)] \tag{23}$$

These are pseudoharmonic potentials that constrain bond lengths (b), bond angles (θ), and the rotamer angles (ϕ, δ) for staggered and eclipsed conformations, and K is a constant. The van der Waals and electrostatic interactions are described by V_{vdW} and V_{coulomb},

$$V_{vdW} = \sum_{\text{pairs } (ij)} \frac{C_{12}}{r_{ij}^{12}} - \frac{C_6}{r_{ij}^6} \tag{24}$$

$$V_{\text{coulomb}} = \sum_{\text{pairs } (ij)} \frac{q_i q_j}{4\pi\varepsilon_0 \varepsilon_r r_{ij}} \tag{25}$$

where Equation (24) is the Lennard–Jones potential, containing repulsive and attractive terms (C is a constant), and Equation (25) describes the coulombic interactions between two charged particles (i, j) with partial charges q that are a distance r_{ij} apart in a dielectric medium described by $\varepsilon_0 \varepsilon_r$. The term V_{NMR} contains the NMR restraints, and has the effect of pulling the protons that show an NOE interaction closer to the measured distance r_{ij}. Similarly, V_{NMR} may also contain J-coupling information by including a torsion term. These potentials are also pseudo harmonic functions of similar form to Equations (21–23). Distance constraints which can be reasonably accurately determined may therefore be defined as Equation (26):

$$V_{\text{NOE}} = \begin{array}{ll} K_1 (r_{ij} - r_{ij}^0)^2 & \text{if} \quad r_{ij} > r_{ij}^0 \\ K_2 (r_{ij} - r_{ij}^0)^2 & \text{if} \quad r_{ij} < r_{ij}^0 \end{array} \tag{26}$$

where r_{ij} and r_{ij}^0 are the calculated and experimental interproton distances respectively, and K_1 and K_2 are force constants given by Equation (27):

$$K_1 = \frac{k_{\text{B}} TS}{[2(\Delta_{ij}^+)^2]} \quad \text{and} \quad K_2 = \frac{k_{\text{B}} TS}{[2(\Delta_{ij}^-)^2]} \tag{27}$$

where k_{B} is Boltzmann's constant, T is the absolute temperature of the simulation (*not* the experiment), S is a scale factor, and Δ_{ij}^+ and Δ_{ij}^- are the positive and negative error estimates, respectively, of r_{ij}. If, however, only ranges of distances can be specified, then the distance restraints are incorporated into a pseudo square-well potential (Equation 28):

$$V_{\text{NOE}} = \begin{array}{ll} K_{\text{NOE}} (r_{ij} - r_{ij}^u)^2 & \text{if} \quad r_{ij} > r_{ij}^u \\ 0 & \text{if} \quad r_{ij}^l \le r_{ij} \le r_{ij}^u \\ K_{\text{NOE}} (r_{ij} - r_{ij}^l)^2 & \text{if} \quad r_{ij} < r_{ij}^l \end{array} \tag{28}$$

where r_{ij}^u and r_{ij}^l are the upper and lower limits, respectively, of the target distances obtained from experiment, and K_{NOE} is the NOE force constant, which is typically chosen to be of the order of $1000\,\text{kJ mol}^{-1}\text{nm}^{-2}$. Similarly, torsion angle restraints can be incorporated into pseudo square-well potentials (Equation 29):

$$V_{\text{tor}} = \begin{array}{ll} K_{\text{tor}} (\phi_i - \phi_i^u)^2 & \text{if} \quad \phi_i > \phi_i^u \\ 0 & \text{if} \quad \phi_i^l \le \phi_i \le \phi_i^u \\ K_{\text{tor}} (\phi_i - \phi_i^l)^2 & \text{if} \quad \phi_i < \phi_i^l \end{array} \tag{29}$$

where ϕ_i^u and ϕ_i^l are the upper and lower limits of the target range of a particular torsion angle obtained from experiment, ϕ_i is its calculated value, and K_{tor} is the torsion force constant, which is typically chosen to be of the order of $4000\,\text{kJ mol}^{-1}\text{rad}^{-2}$. To ensure that the experimental restraints are the dominating factor in determining the conformation of the molecule, it is very important that the force constants for the restraints are set sufficiently high that the experimental data are satisfied within the precision of the measurements. At the same time, the contribution from the empirical energy function should be such that for any individual RMD structure the deviations from ideal geometry are small, and the nonbonded interactions are good (i.e. the Lennard–Jones potential is negative). This can be determined from a few trial calculations. Thus, convergence on the structure is guided by the requirement to minimize NOE or other restraint violations. The number of distance restraint violations N_{viol} is counted when, for example, $r_{ij} \ge r_{ij}^0 + 1$, which would allow for 1 Å fluctuations. Another parameter that can be minimized in addition to N_{viol} is the sum of the distances in excess of the constraints Δr_{viol}, as given by Equation (30):

$$\sum \Delta r_{\text{viol}} = \sum_{k=1}^{N_{\text{viol}}} (r_{ij})_k - [(r_{ij}^0)_k + 1] \tag{30}$$

where the sum runs over all those interproton (or pseudo-atom) distances for which N_{viol} is defined. Although an arbitrary structure may be used for RMD calculation, in practice a starting structure obtained from distance geometry and energy minimization is often used. Because of the kinetic energy present in the protein during the dynamics simulation, the problem of local minima can be overcome relatively easily.

The RMD approach requires a relatively large amount of computation time compared to distance geometry

methods. This problem can be overcome by using a simplified potential energy function, where all nonbonded contact interactions are described by a single van der Waals repulsion term. Also, by using a cut-off distance, in which nonbonded interactions for pairs of atoms that are separated by a distance greater than some reasonable value (e.g. 5–10 Å), the number of nonbonded interactions is decreased significantly.

Simulated annealing[89] involves raising the temperature of the system followed by slow cooling in order to overcome local minima and locate the global minimum region of the target function. It is computationally more efficient than RMD and yields structures of similar quality. The potentials are very similar to RMD and again Newton's laws of motion are solved as a function of time. However, in implementations found in commercial programs, the nonbonded interaction potential is modified so that there is a simple van der Waals repulsion term with a variable force constant K_{rep} (Equation 31):

$$V_{repel} = \begin{cases} 0 & \text{if} \quad r \geq sr_{min} \\ K_{rep}(s^2 r_{min}^2 - r^2)^2 & \text{if} \quad r < sr_{min} \end{cases} \qquad (31)$$

The values of r_{min} are given by the sum of the standard values of the van der Waals radii between two atoms as represented by the Lennard–Jones potential used in, for example, the empirical energy function CHARMM (Chemistry at Harvard Molecular Mechanics). A van de Waals scale factor, s, typically should be set to 0.8 to account for the fact that interatomic separations slightly smaller than the sum of the hard-sphere van der Waals radii can easily occur due to the attractive component of the van der Waals interaction. Further potentials and force constants can be introduced for refinement against chemical shift and torsion angle databases, and for inclusion of residual dipolar couplings.[90]

3.5 Energy Minimization

The next step in biomolecular structure determination is the refinement of the distance geometry-derived Cartesian coordinates. Energy minimization is generally used to find local minima in the potential energy for the structure. Commonly employed energy minimization algorithms[91,92] offer choices of one of the following methods: steepest descent, conjugate gradient (also known as Powell[93]), and Newton–Raphson. All these assume that the energy surface is approximately harmonic, and physically adjust the atomic positions in Cartesian space over the energy surface, deeper into the local potential well. Although the rate of descent for the steepest descent method is initially fast, it is nonconvergent and often results in large oscillations about the minimum. This may lead to structures that have climbed out of the local well to a higher energy point. The conjugate gradient method approaches the minimum more slowly, and results in a converged minimum point energy. However, for very poor starting structures, it is more likely to converge.

In general, for biomolecules, 100 or so steps of steepest descent minimization are followed by 500–1000 steps of either conjugate gradient or modified Newton–Raphson methods. These energy minimization steps can be carried out at a variety of the steps involved in generating NMR structures of biomolecules. Restraints can be included in some of the implementations of these algorithms. In fact, too many minimization steps without restraints (and without including solvent molecules) may lead to structures that are far from either X-ray crystal or NMR structures. Therefore, although these methods are used to generate theoretical model structures, without restraints, their indiscriminate application to biological problems is likely to lead to meaningless structures that are not at all helpful in understanding their function.

Figure 6 The strategy for solving the 3D structure of biomolecules on the basis of NMR data. (Adapted from ref. 8 with permission.)

3.6 Procedure for Structure Determination

The typical procedure in obtaining an NMR structure is as follows. The NMR spectra are assigned using 2D, 3D, and 4D NMR experiments, and from these a list of distance restraints derived from NOEs and/or dipolar couplings are generated, together with torsion angle restraints derived from J couplings and/or dipolar couplings. This list is used to determine a set of NMR force potentials that, together with a seed of randomly generated initial extended chain structures, form the input files for distance geometry and/or RMD/simulated annealing calculations (Figure 6).

When the structures converge on a well-defined structure (the next section provides a definition of ''well-defined''), then either the whole family of structures or a calculated average structure can be subjected to further restrained dynamics or energy minimization, to generate the final structures. Generally it is preferable to keep the whole family of structures, and submit them to the Protein Data Bank as the final structure. Such families inform users of the structural data as to the areas of the structure that are not well-defined. However, if the structures do not converge, then a sometimes lengthy iteration of going back to the original data to check assignments (both in terms of chemical shifts and NOE intensities) and recalculation of structures ensues. This can be supplemented with use of iterative relaxation matrix approaches to back-calculate the NOESY spectra, and comparison with the experimental data can lead to a semi-automated way of recalculating the structures. This method seems to work for relatively small molecules, but generally fails in biomolecules whose M_r exceeds 15 kDa. Refinement of the structure continues until some criteria of accuracy are met.

3.7 Assessing the Accuracy and Precision of the Final Structure

As already discussed, the typical procedure for obtaining NMR structures involves using a large number of different starting structures for the distance geometry and/or RMD/simulated annealing. If a significant fraction of the calculated structures converge, satisfying all the NMR restraints, and show a root-mean-square deviation (RMSD) from each other of less than 2 Å, then this indicates that the calculated structures must be close to the actual structure. The RMSD is generated by superimposing the centroids of the structures, and calculating a rotation that minimizes the overall value (Equation 32):

$$\text{RMSD} = \sqrt{\frac{1}{N}\sum_{i=1}^{N}(r_i - r_i')^2} \qquad (32)$$

where N is the number of atoms being compared, and r_i and r_i' are the atomic coordinates for the standard structure and the rotated structure, respectively. For comparisons of families of NMR structures, each of the structures is rotated so as to provide the best fit with a predetermined member of the family. The RMSD values are reported for all pairwise structure comparisons. If serious violations of the NMR restraints remain, or if the RMSD between the various structures is too large, then reanalysis of the NMR spectra is necessary. A further check can be made using the iterative relaxation matrix approach and back-calculating the NOESY spectrum from the structure. The precision of the measurements, for example how narrowly the bounds for NOE-derived distances are defined, will improve the RMSD between the set of calculated structures and therefore the accuracy of the structure. Those NMR protein structures that show a relatively low level of detail typically have RMSDs of at least 1.5–2 Å. Higher-resolution structures show RMSDs of the order of 0.8 Å for the backbone atoms, 1 Å for backbone atoms plus some interior side-chain atoms, and around 1.5 Å for all the atoms in the molecule. Such improvements in resolution can be attributed in part to the availability of stereospecific assignments, which have the effect of narrowing the distance bounds. Relatively few restraints are sufficient to define the global fold in proteins, whereas the same is not true for nucleic acids, where there are no possible long-range restraints. Here iterative relaxation matrix approaches to refinement of the precision of the distance measurements from NOESY cross-peak volumes is very important.

Another method that is beginning to be used in assessing the accuracy of a structure is the R factor, or structure factor, which, by analogy with the term in X-ray crystallography, is the normalized mean deviation between the structure factors derived from the model and the experimental data. For NMR data, this usually involves[94] a direct measure of the fit between the experimental and theoretical NOE intensities when the final model is subjected to back-calculation of the NOESY spectrum. In its simplest, most general form the NMR R factor is defined as in Equation (33):

$$R = \frac{\sum_{i,j} W_{ij}(\tau_m)\ A_{ij}^{\text{calc}}(\tau_m) - A_{ij}^{\text{exp}}(\tau_m)}{\sum_{i,j} W_{ij}(\tau_m) A_{ij}^{\text{exp}}(\tau_m)} \qquad (33)$$

where $A_{ij}^{\text{calc}}(\tau_m)$ and $A_{ij}^{\text{exp}}(\tau_m)$ are the elements connecting protons i and j of the theoretical and experimental NOE intensity matrices for a given mixing time τ_m. Weight factors $W_{ij}(\tau_m)$ are included to account for measurement errors. A number of other definitions of the R factor have appeared, and some of the available algorithms calculate

several different types of R factor simultaneously. The convergence limit on as low an R factor as achievable in an iterative relaxation matrix structure calculation is usually used as the stopping point for the refinement. However, as for X-ray crystallography, the R factor only measures the agreement of the calculated structure with the experimental data, so that a low value does not necessarily mean an accurate structure if the precision of the measurements is poor. One type of R factor recently introduced[95] that attempts to circumvent this problem relies on cross-validation, which is a statistical method that estimates the quality of the fit to the observed data without making any assumptions about the distribution of errors in the NMR data.

Despite best efforts at obtaining precise distance measurements for use in calculating accurate structures, there are often still regions of a molecular structure for which NMR restraints are absent. These regions are therefore disordered during all the refinement procedures, and it is tempting to suggest that this region has considerable conformational flexibility. In other words, a common argument is that absence of NMR restraints means an absence of structure. But the negative observation of a less accurately determined structure in a certain region (resulting from the lack of NOEs for example) is not sufficient to establish that a structure is disordered and conformationally labile. This can be addressed by measuring backbone dynamics using ^{15}N-labeled protein and measuring heteronuclear ^{15}N T_1, $T_{1\rho}$, and T_2 relaxation rates and ^{1}H–^{15}N NOEs, so that the order parameter (S^2) can be calculated.[96–99] This is a more rigorous way of determining whether molecular motion is the real reason for the absence of NOEs. Similarly, side-chain dynamics can be probed using measurements of ^{13}C T_1, $T_{1\rho}$, and T_2 relaxation rates and ^{1}H–^{13}C NOEs and ^{2}H T_1 and $T_{1\rho}$ relaxation rates.[100,101]

4 OBTAINING LONG-RANGE DISTANCE AND ANGLE INFORMATION

The need for a long-range distance and angle information is clear when liquid-state NMR is only capable of furnishing distances of the order of 5 Å, and angle information for spins involved in direct scalar J-coupling interactions. Here a number of approaches are emerging that have the potential to address this significant shortcoming of NMR as a biomolecular structural technique.

4.1 Use of Shift Tensors to Obtain Torsion Angles

The origin of the chemical shift is that the moving electric charges of the electron cloud around a nucleus induces a local magnetic field which opposes the applied field. Thus the effective field at the nucleus is (Equation 34):

$$\mathbf{B}_{\text{eff}} = \mathbf{B}_0(1 - \sigma_{\text{iso}}) \tag{34}$$

The nucleus is said to be *shielded*, and the extent of the shielding is given by the shielding constant, also called the isotropic chemical shift tensor, σ_{iso}. This is directly related to the electron density ρ at a distance r from the nucleus by Lamb's equation (Equation 35):

$$\sigma_{\text{iso}} = \frac{4\pi e^2}{3mc^2} \int_{-\infty}^{\infty} r\rho(r)\,\mathrm{d}r \tag{35}$$

There are three principal components of the shift tensor, σ_{11}, σ_{22} and σ_{33}, and the isotropic shift tensor σ_{iso} is given by Equation (36):

$$\sigma_{\text{iso}} = \tfrac{1}{3}(\sigma_{11} + \sigma_{22} + \sigma_{33}) \tag{36}$$

The shift tensor σ_{iso} is related to the Larmor frequency w_0 by Equation (37):

$$w_0 = \frac{\gamma}{2\pi}\mathbf{B}_0(1 - \sigma_{\text{iso}}) \tag{37}$$

and to the chemical shift by Equation (38):

$$\delta = 10^6(\sigma_{\text{ref}} - \sigma_{\text{sample}}) \tag{38}$$

By appropriate choice of a coordinate system, the isotropic chemical shift σ_{iso}, which is a 3×3 matrix, or second rank tensor, may be converted to three principal elements, σ_{11}, σ_{22} and σ_{33}, which serve to characterize the 3D nature of the shielding. From these elements it is possible to define the shielding anisotropy $\Delta\sigma$ and the shielding asymmetry parameter η (Equations 39 and 40):

$$\Delta\sigma = \sigma_{33} - \tfrac{1}{2}(\sigma_{11} + \sigma_{22}) \tag{39}$$

$$\eta = \frac{\sigma_{22} - \sigma_{11}}{\sigma_{33} - \sigma_{\text{iso}}} \tag{40}$$

The chemical shielding tensor ellipsoid is illustrated in Figure 7, together with the relationship between the principal axis system and the laboratory frame (the frame in which $\mathbf{B}_0$ resides). The principal elements of the shift tensor can be obtained by rotational side-band intensity analysis.[102] The parameter $\Delta\sigma$ provides an estimate of the departure from spherical symmetry of the electrons around the nucleus.

In solution, the isotropic molecular motion averages the shift anisotropy (see Equation 36), except in cases where there is partial ordering of the sample. In the solid state, the chemical shift anisotropy will be manifested according to the state of the sample:

Figure 7 The chemical shielding ellipsoid, which is used to indicate that different orientations of the magnetic field relative to the molecular framework result in different resonance positions for the same chemical species. (Adapted from ref. 8 with permission.)

1. In a single crystal in a fixed orientation to the magnetic field, a single sharp line will be observed for each magnetically unique orientation of a particular nucleus with respect to the field direction, and the positions of these lines will change as the orientation of the crystal is changed.
2. For a powdered sample, each random crystallite orientation will give rise to a line, and the sum of these generate a broad line, the shape of which will depend on the principal elements of the shielding tensor (Figure 7).[103]

When two of the elements are identical, the shielding pattern is said to be axially symmetric. Such a situation can arise either by chance, or from the presence of molecular motion which partially averages the shift anisotropy in one direction.

When the principal elements of the shift tensor have been determined for a given pair of nuclei, their mutual orientation can be determined relative to the laboratory frame and to the molecular frame, thereby enabling torsion angles to be determined. This can be achieved by relating the tensor orientations of the two nuclei back to the molecular axis, or by fixing one tensor relative to the molecular axis and determining other unknown tensors by measuring some angle-dependent property, such as the dipolar coupling (sections 4.2, 4.3.2, and 4.3.4).

4.2 Use of Residual Dipolar Couplings to Obtain Distance and Angle Restraints

Distance and angle information can be obtained from NMR through the determination of dipolar couplings. The dipole–dipole interaction is averaged to zero in an isotropically tumbling liquid. However, for a biological macromolecule, tumbling can be anisotropic under conditions of high magnetic fields or in the presence of a liquid crystalline phase.[104–108] These methods partially orient the liquid-state sample through the use of lipid bicelles,[109] filamentous phage,[110] viruses,[111] or purple membranes.[112] Under these circumstances, residual dipolar couplings can be measured, which can give restraints relative to a molecular frame, enabling domains to be oriented relative to one another, and leading to more accurate distance measurements. They can be measured using pulse sequences which measure the contribution to J couplings that are due to residual dipolar couplings, such as the in-phase/antiphase (IPAP) HSQC and HNCO pulse sequences.[105,107] Such residual dipolar couplings can then be incorporated into simulated annealing protocols for structure refinement,[108,113] using Equation (41) for dipolar couplings between two nuclei, P and Q, relative to the molecular alignment tensor:

$$D_{\mathrm{PQ}}(\theta,\phi) = \mathbf{S}\frac{\mu_0}{4\pi}\frac{\gamma_{\mathrm{P}}\gamma_{\mathrm{Q}}h}{4\pi^2 r_{\mathrm{PQ}}^3} \times \left\{A_{\mathrm{a}}(3\cos^2\theta - 1) + \frac{3}{2}A_{\mathrm{r}}\sin^2\theta\cos 2\phi\right\} \quad (41)$$

where **S** is the generalized order parameter for internal motion of the PQ vector, γ_{P} and γ_{Q} are the gyromagnetic ratios of P and Q, h is Planck's constant, r_{PQ} is the distance between P and Q, and θ and ϕ are the cylindrical coordinates describing the orientation of the PQ vector in the principal axis system of **A**. Values for the axial (A_{a}) and rhombic (A_{r}) components of **A** depend on the shape of the protein and vary with the bicelle concentration. These approaches are already having a significant impact on NMR structure determination,[90,114–117] and are likely to revolutionize liquid-state biomolecular structure determination in general. However, there still remains the need for accurate distance measurements in larger macromolecular assemblies, or in unoriented soluble proteins whose molecular weight exceeds the current liquid-state NMR limits, and here solid-state NMR has a lot to offer.

4.3 Solid-state Nuclear Magnetic Resonance in Biomolecular Structure Determination

As the dipolar coupling is not averaged to zero in the solid state, it can be a valuable source of distance information from NMR in addition to NOEs. Torsion angles can also be determined very accurately from the angular dependence of the dipolar coupling, and can be used to determine the structure of a small biomolecule. Distances and torsion angles calculated from the measured dipolar coupling constant in the solid

state can be significantly more accurate than distances or angles determined from NOEs and J couplings in solution. For example, distances can be measured with accuracies of the order of ± 0.1–0.5 Å, and angles of the order of $\pm 3°$. The main disadvantage is that currently only pairwise distances or angles between isolated spins can be measured, so that there is a serious paucity of constraints compared with solution-state methods. Therefore, these approaches involve generating a very limited set of accurate torsion angle or distance measurements which can be used to define parts of a molecular structure. Furthermore, in the case of the distance measurement methods, far longer distances (up to 18 Å) can be measured than for NOEs where the limit is about 6 Å. For instance, functionally crucial distances may be measured, such as between a substrate and an enzyme, or a protein and DNA, or an antibody and its antigen. These techniques have also been reviewed elsewhere at greater length.[8,118]

4.3.1 *Homonuclear Dipolar Recoupling to Obtain Distances*

Most modern solid-state NMR approaches reduce linewidths which are broadened by large proton–proton dipolar couplings by use of magic-angle spinning (MAS). This technique causes all the dipolar couplings (both homonuclear and heteronuclear) in the dipolar Hamiltonian to fluctuate sinusoidally during the rotor cycle, so that integrating the Hamiltonian over one rotor cycle gives zero. A number of methods have been introduced recently which selectively reintroduce the dipolar coupling (hence ''recoupling'') for strongly coupled homonuclear spins and use this to measure selected distances in biomolecules, particularly those with $M_r > 50\,000$. Almost all the techniques work by manipulating the dipolar Hamiltonian in such a way that it integrates to a nonzero value over the rotor cycle, scaled by a factor determined by the particular experiment. The first technique, called rotational resonance (or R^2), introduced by Griffin et al.[119,120] relies on the fact that magnetization transfer between two homonuclear spins is most efficient when the chemical shift difference equals an integral of the MAS frequency, which can place the spinning side-band of one resonance overlapping with the isotropic resonance of another.[121] This phenomenon is called the rotational resonance condition, and is given by Equation (42),

$$\Delta v = n w_r \tag{42}$$

where Δv is the chemical shift difference of the cross-relaxing resonances, n is an integer, and w_r is the spinning speed. Clearly the requirement for isotropic resonances to be well separated places some restrictions on the applicability of this method. Griffin et al. made use of this phenomenon using isotopic labels, although others have used it at natural abundance.[122,123] The pulse sequence (Figure 8) involves an exchange time for magnetization transfer to occur. If the two rotationally coupled spins are also close in space, and therefore dipolar recoupled, their resonance intensities will vary as a function of the mixing time due to a transfer of magnetization. When spinning at the $n = 1$ rotational resonance condition, the initial rate of magnetization transfer is dominated by the strength of the dipolar coupling. As the value of n increases, the rate of transfer decreases and contributions from the orientations of the chemical-shift tensors become more significant, making interpretation of the transfer rate more difficult. Therefore the $n = 1$ experiments are the most useful, although it is still necessary to know the isotropic shifts of the two resonances, the zero quantum transverse decay T_2^{ZQ}, the principal values of the shift tensors (which are known for many functional groups[124]) and, less important, the mutual orientation of the two tensors. The zero-quantum T_2^{ZQ} decay influences magnetization transfer, because the difference polarization is continuously exchanged with zero quantum coherence under the influence of dipolar coupling, and may be measured from Hahn spin–echo experiment. Theoretical simulations of strongly coupled sites also predict T_2^{ZQ} and oscillations in the transfer curves that result from the relative orientations of the exchanging sites.[125]

Figure 8 Pulse sequence for rotational resonance experiment. After cross-polarization (CP), the $90°_{-y}$ pulse returns the ^{13}C magnetization to the z axis (a flipback pulse). The weak $180°_{sel}$ inverts selectively one of the two resonances separated by Δv, and after a variable mixing times, τ_m, the spectrum is recorded. (Adapted from ref. 8 with permission.)

As the magnetization transfer is proportional to the dipolar coupling (D), measurement of D can be used to calculate internuclear distance r according to Equation (43):

$$D = \frac{\mu_0}{4\pi} \frac{\gamma_I \gamma_S \hbar}{r^3} \tag{43}$$

where γ_I and γ_S are the gyromagnetic ratios for the two spins involved (in the case of the R^2 experiment, this means two homonuclear spins, so $\gamma_I = \gamma_S$, although obviously this can apply to two heteronuclear spins), $\hbar$ is Planck's constant divided by 2π, and μ_0 is the permittivity of a vacuum. The experimental data fit with simulated curves to an accuracy of ± 0.4 Å for an isolated spin pair (e.g. $^{13}C-^{13}C$ or $^{31}P-^{31}P$), and the limits of distances which may be detected can be as high as 18 Å for $^{19}F-^{19}F$ pairs. These distances can be used as restraints in distance geometry and/or simulated annealing calculations.

A number of other homonuclear recoupling methods have been introduced, including RFDR (rotor-driven dipolar recoupling),[126] SEDRA (simple excitation for the dephasing of rotational amplitudes),[127] DRAMA (dipolar recovery at the magic angle)[128] and its variants,[129,130] MELODRAMA (melding of spin-locking and DRAMA),[131] DRAWS (dipolar recoupling with a windowless sequence),[132] CROWN (combined rotation with nutation),[133] HORROR (homonuclear rotatory resonance),[134] C7 (7-fold symmetric homonuclear recoupling),[135] and POST-C7 (compensated 7-fold symmetric homonuclear recoupling).[136]

4.3.2 Homonuclear Dipolar Recoupling to Obtain Angles

The rotational resonance experiment can also be used to measure torsion angles.[137] At higher orders of the rotational resonance condition, $n \geq 3$, the magnetization exchange rate is not only dependent on the internuclear distances but also very strongly dependent upon the relative orientation of the two chemical shift tensors (provided they are both large). McDermott et al.[138] have used this approach to measure dihedral angles between two adjacent nonprotonated carbons in phosphoglycolate bound to triosephosphate isomerase, to an accuracy of $\pm 10^\circ$. They made use of the fact that the intensity of the zero quantum side-bands depends systematically on the dihedral angle, which can be measured by determining the magnetization exchange rates at $n = 4$.

There are alternative approaches to R^2 for mutually orienting two homonuclear shift tensors, and thereby obtaining torsion angles. There are also new techniques emerging for orienting the chemical shift tensors of two dipolar coupled spins with respect to one another, using magnetization transfer,[139] including rotational resonance,[137,138] or multiple quantum coherence,[140,141] including C7.[142–144]

4.3.3 Heteronuclear Dipolar Recoupling to Obtain Distances

The principal heteronuclear technique introduced by Schaefer et al.[145–147] is called rotational echo double resonance (REDOR), and relies on the dephasing of magnetization of one spin in the presence and absence of dipolar coupling to another heteronucleus, and subsequent refocusing as a function of the MAS frequency. The variation of intensity for the one nucleus in the presence and absence of dephasing of the other nucleus is directly proportional to the dipolar coupling constant. The pulse sequence is outlined in Figure 9.

Figure 9 Pulse sequence for a version of REDOR ^{13}C-NMR. Two equally spaced 180° ^{15}N pulses per rotor period result in dephasing of transverse carbon magnetization produced by cross-polarization (CP) transfer from dipolar-coupled protons. The 180° ^{13}C pulse replaces the ^{15}N pulse in the middle of the dephasing period and refocuses isotropic ^{13}C chemical shift differences at the beginning of data acquisition. High power ^1H-decoupling is maintained throughout the ^{15}N dephasing sequence and the acquisition. (Adapted from ref. 8 with permission.)

The first spectrum is obtained using a standard cross-polarization pulse sequence with a π pulse on the observed nucleus (e.g. ^{13}C) in the middle of the evolution period. During this period, the observable magnetization evolves under the influence of the chemical shifts and the heteronuclear dipolar interaction. The 180° pulse refocuses both interactions, leading to a signal S during the acquisition period. The second spectrum is obtained with an additional train of π pulses on the dipolar-coupled spin (e.g. ^{15}N). These pulses affect the observed signal by preventing rotational refocusing of the dipolar interaction. The magnetization is therefore not completely refocused, and the signal intensity drops by an amount ΔS. For weak dipolar coupling, the change in signal intensity is related to the distance between the coupled spins by Equation (44)

$$\frac{\Delta S}{S} = KD^2 N_c^2 \nu_r^{-2} \tag{44}$$

where N_c is the number of rotor cycles during the evolution period, ν_r is the spinning speed, D is the

dipolar coupling, and K is a dimensionless constant. If performed at relatively slow spinning speeds and over several rotor cycles, the size of the difference signal can be increased. This experiment therefore yields the internuclear distance, which for an isolated spin pair (e.g. $^{13}C-^{15}N$ or $^{31}P-^{13}C$) can be determined to an accuracy of around ± 0.1 Å.

One advantage this experiment has over the current homonuclear methods is that a universal curve can be used for the calculation of distances. There is no dependence on the values or orientations of the chemical shift tensors, or on the zero-quantum T_2^{ZQ}. Therefore once a particular instrument has been calibrated with a known sample, such a curve can be used to read off dipolar couplings directly. Furthermore, the distances that can be measured can be quite considerable, for example <5 Å for $^{13}C-^{15}N$, <8 Å for $^{13}C-^{31}P$, and <12 Å for $^{13}C-^{19}F$. Also REDOR can be applied[148–153] to quadrupolar nuclei, for example ^{2}H and ^{14}N.

Other variants of REDOR include experiments involving three or more S spins, such as the transferred-echo double resonance (TEDOR) experiment,[154] which can be used to edit out the natural abundance background signals by selecting unique spin triplets. A third rare spin, such as ^{2}H, ^{19}F, or ^{31}P, is used to distinguish the signal arising from a specific $^{13}C-^{15}N$ pair from that of the natural abundance background, although they require specialized quadruple resonance instrumental capabilities. Another interesting development has been the application by Mueller et al.[155,156] of a Bessel function transform to deconvolute multiple time-dependent dephasing signals, and thereby measure multiple dipolar couplings simultaneously.[157]

The REDOR technique has been further developed, including the REDOR/TOSS (total side-band suppression) pulse sequence,[158,159] alternative phase-cycling schemes,[160–164] and more recently the REDOR/TPPM (two-pulse phase modulation) pulse sequence.[165] Finally, the approach called REDOR-editing[166] can be used to edit a spectrum with a large natural abundance background with respect to a dipolar coupled spin pair that are unique to a biological molecule.

4.3.4 Heteronuclear Dipolar Recoupling to Obtain Angles

This method was developed by Opella, Cross et al., and determines the torsion angles, for example in the polypeptide backbone of a protein, as a means to determine structure based solely on orientational restraints.[167–169] We will consider the theory of this technique as applied to proteins. Although it could be applied to other classes of biomolecules such as DNA, to date its use has been limited primarily to membrane proteins.

The α carbons of adjacent amino acids in a polypeptide chain are joined by the amide C–N bonds. The six atoms that form this peptide linkage lie roughly in a plane, and the relative orientation of adjacent planes is defined by the ϕ and ψ torsion angles (see Figure 10). The secondary structure of the peptide backbone can be determined by establishing the sequential orientation of each peptide plane relative to a common axis.

Measurements of both the dipolar and chemical shift interactions are necessary to limit the number of possible orientations and define the peptide structure.[167,169–171] The orientation dependence of the dipolar interaction is given by Equation (45):

$$\Delta v = D(3\cos^2\theta - 1) \tag{45}$$

where Δv is the observed dipolar splitting, D is the dipolar coupling constant, and θ is the angle between the internuclear vector connecting the spins and the external magnetic field. The dipolar interactions point along the bond axes and are axially symmetric. The observed dipolar splitting ranges from zero for bonds aligned at the magic angle, to $2D$ for bonds parallel to the z axis of the magnetic field. One of the problems in determining peptide plane orientations is that the experimental Δv specifies two or four different values for θ depending on the size of D relative to Δv. Consequently, several bond orientations need to be measured to arrive at a unique solution for the peptide-plane orientation. The $^{15}N-^{1}H$ and $^{15}N-^{13}C$ bond orientations are the most readily measured dipolar interactions because they involve spin-$\frac{1}{2}$ nuclei, although ^{14}N quadrupole and dipole splittings can also be measured and used as orientation restraints.[172,173] Additional restraints for peptide-plane orientations can be derived from the amide ^{15}N and carbonyl ^{13}C chemical-shift tensors. The orientation dependence of the chemical

Figure 10 Illustration of the peptide planes of a dipeptide and the appropriate orientations of the amide ^{15}N and carbonyl ^{13}C chemical shift tensors with respect to the molecular frame. The ϕ and ψ angles define the orientation of the planar peptide linkages and are determined by measuring the N–C and N–H bond orientations, as well as the orientation of the ^{15}N and ^{13}C shift tensors. (Reprinted from ref. 103 with permission.)

shift interaction is given by Equation (46):

$$\sigma = \sigma_{11}\cos^2\alpha\sin^2\beta + \sigma_{22}\sin^2\alpha\cos^2\beta + \sigma_{33}\cos^2\beta \quad (46)$$

where σ is the observed chemical shift, σ_{11}, σ_{22}, and σ_{33} are the principal components of the chemical shift tensor, and α and β are the Euler angles relating the principal axis system of the chemical-shift tensor to the laboratory frame (Figure 7). Although the dipolar interaction points along the internuclear axis and is related to the magnetic field axis by a single rotation about an angle θ, the orientation of the chemical-shift tensor must be determined relative to a molecular axis and relative to the magnetic field axis. The standard approach for establishing the orientation of a chemical-shift tensor relative to a molecular axis system has been through NMR studies of single crystals in which the molecular axis orientation can be determined independently using X-ray methods.[174–176] More recent methods have been developed that make use of the axial orientation of dipolar interactions as a convenient frame of reference.[177–180]

5 EXAMPLES OF BIOMOLECULAR NUCLEAR MAGNETIC RESONANCE

There are essentially limitless ways that NMR spectroscopy can be and has been applied to the study of biomolecules. Rather than attempting to provide an exhaustive treatment here (which has been covered more fully elsewhere[8]), this section highlights a few examples to illustrate the use of NMR to study proteins, nucleic acids and enzymes, and one elegant example from the literature of a membrane protein structure determination.

5.1 Proteins and Nucleic Acids

A brief example of the ways in which NMR can be applied to the structure determination of a protein–DNA complex is recent work on the high-mobility group (HMG) I/Y protein. Using high-resolution multinuclear multidimensional solution-state NMR spectroscopy, the structure of the protein–DNA complex of the HMG I/Y protein complexed to a 12-mer oligonucleotide was determined.[181] This protein is relatively small (M_r = 11 kDa, 107 residues), so at first sight would be amenable to standard ^{1}H-NMR COSY and NOESY approaches outlined in section 2.3.1. However this protein turns out to be unusual in that, in the absence of DNA, the protein is largely unstructured, and contains a large number of lysine, arginine, and proline residues, making assignments difficult. In the presence of DNA, the protein becomes partially structured, and binds largely to the minor groove of DNA, although it still remains a difficult assignment problem, particularly when complexed to 12-mer DNA. Therefore it was necessary to generate ^{13}C/^{15}N-labeled protein truncated to contain two of the three DNA-binding domains (DBDs) (Figure 11). A large number of standard 3D NMR experiments were carried out on the protein complexed with 12-mer DNA (Table 1).

Representative strip plots from 3D CBCANH and CBCA(CO)NH spectra are shown in Figure 12. Use

of ^{13}C-separated, ^{12}C-filtered, and ^{15}N-separated, ^{12}C-filtered NOESY experiments[182–191] has enabled identification of over 100 intermolecular NOE contacts between the protein and the DNA (Figure 13). These experiments rely on the ability to select either the species that is isotopically labeled, or the species that is not, as illustrated in Figure 14. Using ^{12}C/^{12}C-filtered NOESY experiments the DNA spectrum was assigned. A representative region is shown in Figure 15. One discovery with this sample was that only one HMG-I(Y) DBD was bound to the 12-mer DNA operator at any one time, with a difference between the two bonding affinities for the two DBDs in the truncated protein used for the structure determination. The structures of each DBD bound to DNA have been determined, as illustrated in Figure 16. A summary of the structural statistics is given in Table 2. Note that the region between the two DBDs is involved in protein–protein interactions, but because the DNA operator used in this structure determination was too short, no structural information could be obtained for this region.[181]

Figure 13 Summary of the DNA contacts involving DBD2 and DBD3. The DNA is represented as a cylindrical projection viewed from the minor groove side. Bases are indicated as thick lines, the deoxyribose sugar rings as pentagons, and the phosphates as circles. Contacts involving amino acid side-chains and backbone amides are indicated by solid and dashed arrows, respectively. (Adapted from ref. 181 with permission.)

5.2 Enzymes

In addition to NMR being useful in determining protein structure, it can be used to probe functionally critical regions of proteins, such as encountered in the active site of an enzyme. An example of this is work on the enzyme 5-enolpyruvyl-shikimate-3-phosphate (EPSP) synthase, which catalyzes the reaction outlined in Scheme 1; EPSP synthase is of interest as the primary target for the broad-spectrum herbicide glyphosate (*N*-(phosphonomethyl)glycine (GLP)) which is the principal ingredient of Roundup®.

This enzyme has been extensively studied by kinetic and biophysical methods since the late 1980s. Direct observation of the enzyme-bound intermediate complex by solution-state NMR was first reported in 1989,[192,193] and later confirmed by another laboratory.[194] This is illustrated in Figure 17. Some site-directed mutants of the enzyme by steady-state kinetics, kinetic isotope effect analysis, fluorescence spectroscopy, and solution-state ^{31}P-, ^{13}C-, and ^{15}N-NMR spectroscopy have since been characterized.[195–198] The enzyme has also been characterized qualitatively by solid-state REDOR NMR spectroscopy,[199] and a quantitative REDOR study has been completed.[200]

In time-resolved solid-state NMR, the enzyme and substrate are mixed together very rapidly and fired into a secondary cryogen such as liquid propane cooled to about 85 K.[201–206] This rapid freeze–quench generates a snow that can be packed in a solid-state NMR rotor for subsequent NMR analysis. In this manner enzymatic

The backbone (N, Cα, C) atoms of the DBDs are shown in yellow; side-chains of Arg8, Pro9, Arg10, Arg12, Pro13, Lys17 and Asn18 for DBD2, and Pro35, Arg36, Arg38 and Pro39 of DBD3 are shown in red; and the DNA is shown in blue. (Adapted from ref. 181 with permission.)

reactions can be stopped with a time resolution of about 6 ms along the reaction coordinate, and the relatively stable and therefore populated ground-state species examined as a function of time. Concerns about the fate of the protein under these conditions of freezing have been addressed,[207,208] and at the protein concentrations and freezing rates (10^5 K s^{-1}, or millisecond time regime) that were employed, there is significant dispersal of the solute in the frozen water.[204] Furthermore the frozen water is probably largely amorphous,[204] with the protein itself acting in a similar manner to a cryoprotectant,[209] thereby reducing the formation of hexagonal ice that is detrimental to the protein. The specific activity of EPSP synthase employed in these freeze–quench experiments was assayed before and after rapid freezing and found to be unchanged at the high protein concentrations used. The time-resolved solid-state NMR technique has been successfully applied to EPSP synthase[201–203,205] and uridine diphosphate *N*-acetyl glucosamine enolpyruvyl transferase (UDP-NAG EPT).[206] The work with EPSP synthase (Figure 18) showed that it was possible to use solid-state NMR to follow the build-up of the intermediate (with concomitant loss of substrate and build-up of product) under pre-steady-state kinetic conditions.[205] These studies confirmed the intermediates reported by Anderson and Johnson,[210] determined by chemical quench methods.

Time-resolved solid-state NMR has been coupled with REDOR for qualitative structural studies of complexes of EPSP synthase[199] and UDP-NAG EPT,[211] and REDOR used as an editing technique in combination with time-resolved solid-state NMR to detect the transient enzyme–intermediate of EPSP synthase.[166] REDOR dephasing on a nucleus unique to the substrate or intermediate can be used to illuminate a sphere of a radius defined by the limit of the technique, and to light up selected residues within the vicinity if they are appropriately isotopically labeled (Figure 19). Following a report for a new mechanism for EPSP synthase,[212] quantitative REDOR measurements on several species formed during the enzymatic reaction proved the proposed new mechanism to be incorrect.[200] The X-ray structure of the unliganded form of EPSP synthase has been reported,[213] but to date there has been no published report of the structure in the presence of substrates. It is known that substrates induce a conformational change, and it is thought that the protein shifts to a closed form. Therefore, several attempts have been made to characterize the structure of the closed conformation by NMR.[214–218] In order to carry out intramolecular and intermolecular distance measurements by dipolar recoupling techniques, it is necessary to have a fixed site on the protein whose location has been established unambiguously, and make measurements either within the protein or to substrates whose location is also known. The weakness of some work in this field is ambiguity as to the location of one or other partner in the dipolar-coupled spin pair. This is a nontrivial problem, because techniques for site-specific isotopic labeling of proteins are generally insufficiently developed to be able to generate NMR quantities of sample. Uniform isotopic labeling is problematic because making sequence-specific assignments by solid-state NMR is not yet possible for proteins of 46 kDa. This laboratory is in the process of introducing a number of novel approaches to site-specific labeling and carrying out dipolar recoupling measurements to generate a limited set of

[a] ⟨SA⟩ is the final set of 35 simulated annealing structures for each complex. $\overline{SA}$ are the mean structures for the two complexes obtained by averaging the coordinates of the individual SA structures best fitted to each other (with respect to residues 6–19 of the protein DBD2 and residues 32–41 of the protein DBD3, and base pairs 1–12 of the DNA). $(\overline{SA})_{\mathrm{r}}$ are the restrained regularized mean coordinates for the two complexes obtained by restrained regularization of the mean SA coordinates. The number of terms for the various restraints is given in parentheses with the first number referring to the DBD2–DNA complex and the second to the DBD3–DNA complex.

[b] None of the structures exhibited distance violations greater than 0.5 Å, dihedral angle violations greater than 5°, $^3J_{\mathrm{HN}_\alpha}$ coupling constant violations greater than 2 Hz, or $^3J_{\mathrm{coco}}$ coupling constant violations greater than 0.5 Hz.

[c] The number of NOEs involving $(\quad r^{-6})^{-1/6}$ sum restraints to multiple DNA protons is 27 for the DBD2–DNA complex and nine for the DBD3–DNA complex. The effect of such restraints is to permit a close interproton distance contact to be obtained from a proton of the protein to whichever of the protons on the DNA is specified in the restraint, the $(\quad r^{-6})^{-1/6}$ sum restraint being satisfied providing only that at least one of these DNA protons is close to the specified proton of the protein.

[d] The hydrogen bond restraints within the DNA were used to maintain Watson–Crick base pairing.

[e] The Nζ atom of a lysine or guanidino nitrogen atoms of arginines were restrained within 7 Å of a DNA phosphate atom when NOEs from a residue (Lys7, Arg8, Lys14, Lys17, Lys19, Arg33 and Lys41) or when structure calculations and ^{15}N relaxation measurements (Lys34 and Lys40) indicated that residue interacts with a DNA phosphate. $(\quad r^{-6})^{-1/6}$ sum restraints were used and in each case a choice of two adjacent phosphate atoms was given.

[f] In the final stages of the structure calculations two types of repulsive distance restraints, with a lower bound of 4 Å (and an unrestrained upper bound), were introduced to facilitate convergence. First, repulsive distance restraints were used to prevent energetically unfavorable proximity of hydrogen bond donors to other donors, and hydrogen bond acceptor groups to other acceptors: there were 11 such restraints for the DBD2–DNA complex and 10 for the DBD3–DNA complex. Second, a small number of repulsive restraints were also used to prevent structures being generated which predicted short interproton distances (<3 Å) for which no corresponding NOEs could be observed: there were nine such restraints for the DBD2–DNA complex and 18 for the DBD3–DNA complex.

[g] The improper torsion restraints serve to maintain planarity and chirality.

[h] E_{L-J} is the calculated Lennard–Jones van der Waals energy and is not included in the target function for simulated annealing or restrained minimization.

[i] The precision of the coordinates is defined as the average atomic RMS difference between the 35 individual simulated annealing structures of each complex and the mean coordinates $\overline{SA}$. The values refer to residues 6–19 and 32–41 of DBD2 and DBD3, respectively, and to base pairs 1–12 of the DNA.

Scheme 1

accurate long-range distance restraints. These are being used in conjunction with short-range NOE-derived distance restraints from solution-state NMR data to solve the structure of the closed conformation of EPSP synthase. Figure 20 shows the HSQC spectrum of an N-terminal fragment of EPSP synthase, and Figure 21 shows the divide-and-conquer strategy taken to solve such a large protein structure.

5.3 Membranes

As membranes and membrane proteins cannot easily be crystallized, NMR spectroscopy is a particularly powerful method for probing their structure and function.[219–221] This section considers the membrane protein gramicidin A, whose structure has been determined in the presence of lipid bilayers.

Gramicidin A is a small hydrophobic peptide composed of 15 alternating L- and D-amino acids ($M_r \approx$ 1600).[222] The peptide dimerizes and forms channels that conduct monovalent cations. There are substantial differences between two X-ray crystal structures of the peptide,[223,224] and the bilayer structure that has been proposed on the basis of circular dichroism

Figure 17 ^{1}H-decoupled ^{13}C solution-state NMR spectrum of EPSP synthase plus substrates (S3P, shikimate-3-phosphate, and [2,3-$^{13}C_2$]PEP, phosphoenolpyruvate) under equilibrium conditions, showing the resonances due to the transient enzyme–intermediate.

Figure 18 Time-resolved solid-state NMR spectra of the enzyme EPSP synthase plus [^{13}C]-labeled substrate PEP at 233 K, showing the transient formation of the enzyme–intermediate and the formation of product (EPSP) as a function of reaction time. (Adapted from ref. 205 with permission.)

Figure 19 Nitrogen-15-detected, ^{31}P-dephased CP/MAS solid-state REDOR difference (ΔS) NMR spectra of [U–^{15}N]EPSP synthase • S3P plus a variety of inhibitors/substrates: (curve a) GLP at 295K; (b) 3-(*Z*)-fluoro-PEP at 273K; (c) [2-^{13}C]PEP under time-resolved conditions at 223K; (d) the full echo spectrum (S_0) of the sample in (a). Resonances due to a subset of lysine and arginine residues within a 6-Å radius of the substrates suggest that these residues are located in the enzyme-active site. A histidine residue putatively located in the enzyme-active site is clearly not detectable. Unfortunately, although the numbers of proximal lysine and arginine residues can be estimated, no site-specific assignments can be made from these data. (Adapted from ref. 192 with permission.)

Figure 20 The ^{15}N-HSQC of the N-terminal domain of EPSP synthase. The spectrum displays reasonably good dispersion and resolution for a 23-kDa protein (the size of the N-terminal fragment). However, even when spread in three dimensions, as with an HNCO experiment, it is not sufficiently well-resolved for a complete assignment. Deuterium labeling is necessary to achieve adequate resolution.

measurements. Such a controversy is amenable to solution by NMR methods.

Cross et al. have conducted a set of experiments using orientation-dependent solid-state NMR studies to address the structure of gramicidin in membranes.[170,225–227] They examined by ^{15}N- and ^{13}C-NMR samples of gramicidin, specifically [^{15}N]- and [^{13}C]-labeled at particular residues, and oriented between glass plates in lipid bilayers. They succeeded in determining the structure by measurement of dipolar splittings and calculating ϕ and ψ torsion angles. Figure 22 shows the spectra from gramicidin, ^{15}N-labeled at Ala3 and Leu4. The measurements are of the Gly2–Ala3 and Ala3–Leu4 peptide bonds and the dipolar splittings ($\Delta\nu$) of the amide ^{15}N resonances resulting from the directly bonded carbonyl carbons. The top spectra show the spectra of oriented gramicidin singly ^{15}N-labeled at the amide nitrogens of Ala3 (left) and Leu4 (right), and the lower spectra show the dipolar splitting of the ^{15}N by ^{13}C when the peptide bonds are doubly labeled. The observed dipolar splittings are 670 Hz for the ^{13}C-Gly2–^{15}N-Ala3 bond and 820 Hz for the ^{13}C-Ala3–^{15}N-Leu4 bond. An accurate

Figure 21 The divide-and-conquer strategy for attempting to solve the solution-state NMR structure of EPSP synthase. The N- and C-terminal domains are expressed separately, and after reconstitution can be isotopically labeled separately, thereby halving the resonance overlap problem for this 46-kDa protein.

Figure 22 ^{15}N spectra of gramicidin A in DMPC (dimyristoylphosphatidylcholine) bilayers. The top spectra are of gramicidin singly labeled with ^{15}N at the amides of (a) Ala3 and (b) Leu4, and the bottom spectra illustrate the dipolar splitting observed when the peptide bonds are doubly labeled with ^{13}C. (Reprinted from ref. 170 with permission.)

Figure 23 Two possible structures for the peptide planes at Ala3 in gramicidin A. Both correspond to right-handed β-type helices but differ in the orientation of the Ala3 carbonyl group, which points toward the gramicidin channel axis (*left*) or away from it (*right*). (Reprinted from ref. 170 with permission.)

bond length is the only additional information needed to calculate the angle θ. A 1.34-Å C–N bond length taken from the crystal structure of alanylalanine translates into a dipolar coupling constant D of 1.26 kHz, so from Equation (45), these data define four possible orientations for each C–N bond because D is larger than the observed splittings.

To limit these possibilities, independent restraints on the peptide plane orientations are obtained from the ^{15}N–^{1}H dipolar couplings and the ^{15}N chemical shift tensor. The ^{15}N–^{1}H dipolar couplings are determined using separated local field experiments.[228–232] These experiments are designed to separate the dipolar couplings from the chemical shifts. They can also be used to relate the chemical shift and dipolar coupling tensors and, as the latter is readily related to the molecular coordinate system, the orientation of the principal components of the shift anisotropy can be determined directly. In gramicidin, the separated local field experiments yield only two possible orientations for each N–H bond, because the ^{15}N–^{1}H dipolar coupling constant is smaller than the observed splittings. As the orientation of the ^{15}N chemical shift tensor relative to the molecular frame has been established independently by reference to model compounds,[177–180,229] the observed ^{15}N chemical shifts provide a way to discriminate between several of the orientations of the N–H and N–C bonds implied by the dipolar couplings. These data, together with additional geometric restraints, define two possible sets of torsion angles for the Ala3 position with errors in the ϕ and ψ angles of $\pm 6^\circ$ and $\pm 5^\circ$ respectively (Figure 23).

The two structures defined by the Ala3 torsion angles are right-handed β-type helices. The difference between the two structures is the orientation of the carbonyl group with respect to the channel axis, which in the upper structure (a) points towards the channel ($\psi = 153^\circ$) and in the lower structure (b) points away from it ($\psi = 122^\circ$). Structure (a) is the favored model because it is biologically sensible, because the selectivity of cations over anions by gramicidin might arise because of the partial negative charges of the backbone carbonyls, which could solvate the cations after they have been stripped of water as they enter the channel.

An alternative approach has been adopted by Schaefer et al.,[233] who used 2D REDOR on Val1-[1-^{13}C]Gly2-[^{15}N]Ala3-gramicidin A in multilamellar dispersions

of DMPC to measure dipolar couplings and infer from these four possible angles between the Gly2-Ala3 $^{13}C-^{15}N$ peptide bond. This information supported a right-handed single-stranded helical dimer as a structural model for gramicidin in multilamellar dispersions.

We have given a detailed description of how torsion angle restraints were derived for one set of dipolar splittings. Cross et al.[234–237] have carried out a systematic determination of the structure of the backbone and side-chains for gramicidin in a lipid environment using 141 orientational restraints derived from measurements of ^{15}N chemical shift anisotropy, $^{15}N-^{1}H$ and $^{15}N-^{13}C$ dipolar splitting, and ^{2}H quadrupole splitting. The final structure, shown in Figure 24, was calculated using an algorithm similar to simulated annealing on a set of 40 random structures, and had RMSDs of $\pm 5^{\circ}$, which reflects the very high precision of the solid-state NMR measurements.

Figure 24 Structure of gramicidin A in a membrane bilayer as determined by solid-state NMR.

ACKNOWLEDGMENTS

I should like to thank members of my research group past and present (Paul Barlow, Richard Appleyard, Wendy Shuttleworth, Cecilia Ramilo, Yan Li, Jaroslav Zajicek, Tatyana Igumenova, Dan Mitchell, David Jakeman, Greg Helms, and Melissa Pohl) for their help with much of the work described here. I should also like to acknowledge Angela Gronenborn, Marius Clore, Jeff Huth, Carole Bewley, Dan Garrett, Frank Delaglio (The National Institutes of Health) and Mark Nissen and Ray Reeves (WSU) for their kind help. This work was supported by NIH grant GM43215. The WSU NMR Center equipment was supported by NIH grants RR0631401 and RR12948, and NSF grants CHE-9115282 and DBI-9604689.

ABBREVIATIONS AND ACRONYMS

C7	7-Fold Symmetric Homonuclear Recoupling
CHARMM	Chemistry at Harvard Molecular Mechanics
COSY	Correlation Spectroscopy
CP/MAS	Cross-polarization/Magic-angle Spinning
CROWN	Combined Rotation with Nutation
DBD	DNA-binding Domain
DMPC	Dimyristoylphosphatidylcholine
DQFCOSY	Double-quantum-filtered Correlation Spectroscopy
DRAMA	Dipolar Recovery at the Magic Angle
DRAWS	Dipolar Recoupling with a Windowless Sequence
ECOSY	Exclusive Correlation Spectroscopy
EPSP	5-Enolpyruvyl-shikimate-3-phosphate
GLP	*N*-(Phosphonomethyl)glycine
HMG	High-mobility Group
HMQC	Heteronuclear Multiple Quantum Coherence
HOHAHA	Homonuclear Hartmann–Hahn
HORROR	Homonuclear Rotatory Resonance
HSQC	Heteronuclear Single Quantum Coherence
INEPT	Insensitive Nuclear Enhancement by Polarization Transfer
IPAP	In-phase/Antiphase
MAS	Magic-angle Spinning
MELODRAMA	Melding of Spin-locking and DRAMA

NMR	Nuclear Magnetic Resonance
NOE	Nuclear Overhauser Effect
NOESY	Nuclear Overhauser Effect Spectroscopy
PECOSY	Primitive Exclusive Correlation Spectroscopy

Raman spectroscopy (RS) is a vibrational spectroscopy technique, based on the phenomenon of inelastic light scattering from matter (the Raman effect). It is an irreplaceable tool for the study of biological events at the molecular level and for identification of biomolecules. There are several reasons for this. First of all, RS measures the vibrations of atoms. This implies that the positions of the bands, widths and intensities are sensitive to the molecular structure, and minor perturbations induced by intramolecular or intermolecular interactions can easily be followed. Vibrations of some molecular groups are very characteristic (characteristic vibrations) and therefore can be used for the identification of certain groups or even whole molecules. In addition, work using isotope labeling, model compounds, site-directed mutagenesis and normal coordinate analysis has led to the identification of so-called marker bands, which serve as a bridge in establishing spectrum–structure correlations. Second, water causes weak Raman scattering, and consequently biomolecules can be studied in their natural environment without solvent interference. The third reason for the growing interest in RS is related to the considerable intensity enhancement (up to 10^6) observable in resonance Raman spectroscopy (RRS) and surface-enhanced Raman spectroscopy (SERS). Important structural units, such as chromophoric active centers, aromatic amino acid residues, bases of nucleic acids, and peptide bonds, can be studied selectively by exploring the resonance Raman (RR) phenomenon and tuning the excitation wavelength (λ_{ex}) into the electronic absorption band of certain structural elements. Such an approach allows the major problem in vibrational spectroscopy of biomolecules to be overcome – namely interpretation difficulties due to overlapping of numerous bands. Because the Raman effect is inherently weak, the future for analytical applications is closely connected with both RRS and SERS. The combination of these two methods might be especially productive. Fourthly, because the Raman effect is instantaneous (timescale in the order of 10^{-14} s), and due to the recent advances in laser technology, the time-resolved action of biomolecules down to picosecond resolution can be followed, retaining the value of structural information. The ability to focus a laser beam down to the dimensions of λ_{ex} is the fifth advantage of RS. Combined with RRS or SERS, this approach allows the composition of a single living cell to be analyzed.

To explore fully the advantages of RS, the limitations of the technique must also be considered. First of all, the probability of Raman scattering is very low, so the effect is weak and high concentrations of biomolecules are required. Secondly, in RR experiments excitation within the electronic absorption band often causes photodegradation of the active center in the biomolecule. To avoid such problems, low laser powers, moving samples and independent inspection of the sample integrity are often employed. The same problems are also present in the SERS field. Overheating by the laser beam could be an obstacle in Fourier transform Raman (FTR) studies. Finally, many active centers in biomolecules, or impurities in the sample, exhibit intense fluorescence (Fl), obscuring the Raman spectra.

1 INTRODUCTION

The Raman effect arises from the interaction of incident photons with electrons of the matter under investigation. During this interaction the photons can lose (Stokes' process) or gain (anti-Stokes' process) energy equal to the vibrational energy of the atoms. Consequently the vibrational energy of the atoms increases or decreases. Such communication is possible for the motions of atoms, which modulate the polarizability of the molecule. Intense Raman bands will be observed from nonpolar groups, particularly aromatic rings, the vibrations of which produce considerable modulation of polarizability. The resulting Raman spectrum, presented in wavenumbers (cm^{-1}) as the difference between the excited and emitted photon energy, is the vibrational spectrum of the molecule. The effect is very weak, because the energy exchange probability is low. Only one in $\sim 10^8$ of the incident laser photons is converted to a Raman photon.[1] The timescale of the scattering process is in the order of 10^{-14} s, so the effect is extremely fast.[2] In the Raman process it is important that the vibrations of the atoms are not probed directly by the incident photons, but through the interaction with the electron cloud. Thus the state of the electrons is also significant and when the energy of incident photons approaches the electronic transition the intensity in Raman spectra is enhanced up to 10^6 times (RR effect).[3] As we will see this unique possibility determines the face of modern biomolecular RS.[1–9]

RS has the following main advantages which make it attractive for biologists:[1–8]

(1) structural sensitivity
(2) intrinsic weak scattering from water
(3) RR and surface-enhanced Raman (SER) phenomenon
(4) possibility to design various kinds of time-resolved experiments with picosecond resolution
(5) possibility to focus laser beam down to the dimensions of λ_{ex}.

Vibrations of atoms depend on the mass and force field. Even minor perturbations in the force field induced by intermolecular or intramolecular interactions are reflected in the spectra, permitting the analysis of structural conformations, bonding strength, and phase transitions. In addition, isotopic labeling perturbs the mass of the system and the location of particular vibrational modes in the spectra can be identified. The motions of atoms in some groups are typical of that particular group, and are hardly affected by the rest of molecule or the environment (characteristic vibrations).[1] Such bands are very useful for instantaneous identification of certain atomic groups in a biomolecule from its spectrum. Tremendous efforts in establishing correlations between spectra and structure, using isotope labeling, model compounds, site-directed mutagenesis and normal coordinate analysis, have led to the identification of certain marker bands, whose position or intensity is directly dependent on the structure and state of the particular group. For example, marker bands provide information on the redox and spin state of the heme group in heme proteins,[7] the secondary structure of polypeptides,[6,7] the state and bonding of amino acid residues,[6] the structure and stacking of nucleic acid bases,[6] and melting phenomena in phospholipid bilayers.[6,7] Structural transformations of biomolecules can be followed by RS in water, i.e. in their natural environment, without serious interference from the solvent. Water causes weak Raman scattering, since vibrations of the highly polar O–H bonds produce only minor polarizability changes. Although Raman spectra mainly contain structural information, the application of conventional RS to real systems is hindered by the complexity of biomolecules. Indeed, proteins routinely contain thousands of atoms. Because the number of normal vibrations for an N-atom molecule is $3N - 6$ (or $3N - 5$ for linear molecules), it is clear that in general spectra contain too much information and consist of many overlapping bands, which cause serious interpretation problems. Fortunately, resonance enhancement (when λ_{ex} lies within the electronic absorption band) and surface enhancement (at roughened Ag, Au and Cu surfaces) effects have been discovered.[9] In RR studies only the vibrations of chromophoric groups are enhanced in intensity (up to 10^6 times), considerably simplifying the spectra. Because different structural units exhibit absorption at different wavelengths, tuning the λ_{ex} makes it possible to selectively probe each unit. Combination of surface and resonance enhancements in surface-enhanced resonance Raman spectroscopy (SERRS) appears extremely promising for analytical purposes, as in some cases concentrations of analytes can be reduced down to $\sim 10^{-10}$ M, and also because of considerable Fl damping. Reports on the detection of single dye molecules have appeared.[10,11] Unlike Fl studies, it is important that the vibrational spectrum from a single molecule contains structural information and characteristic vibrations. The development of reliable and more reproducible sample preparation protocols will expand the analytical applications. The function of biomolecules cannot be understood without knowledge of the evolution of structural transformations over time, as well as the formation of various transient states and species. Time-resolved RS[9] is particularly attractive for fundamental biophysical and biochemical studies because of the combination of molecular level information intrinsic to vibrational spectroscopy with time resolution from milliseconds to picoseconds. Events faster then 1 ps can

also be followed by time-resolved RS, although due to the uncertainty principle the spectral resolution will be reduced. Achievements in this field of RS are directly connected to recent developments in pulsed laser technology. Another field of biospectroscopical research has emerged from the combination of vibrational information with spatial resolution, in the form of micro-Raman spectroscopy (MRS).[9] The laser beam can be focused to the dimensions of light wavelength. Consequently, spatial resolution depends on the wavelength of λ_{ex}. For biologists this opens the possibility of examining compositions of the components of living cells. The combination of RR and/or SER effects with MRS appears to be extremely promising for clinical research.[12]

The advantages of RS for biomolecular studies cannot be fully explored without considering the following main limitations:[1,2,9]

(1) Raman scattering is a weak phenomenon;
(2) the sample may undergo photodegradation by the laser beam;
(3) the sample may be heated by the laser beam;
(4) Fl.

Because Raman scattering is weak, high concentrations of the biomolecules are required. Typical concentrations of nucleotide or peptide groups in nonresonance RS should be in the order of 0.03–0.1 M.[13] In RRS and SERS these concentrations can typically be reduced down to 10^{-8}–10^{-5} M. However, the influence of the laser beam on the sample must be very seriously considered in RRS and SERS experiments. Absorption of photons by the molecular group under investigation (in RRS) or by the surface (in SERS) often leads to photodegradation or denaturation of the biomolecule due to the increased temperature. Overheating problems also should be considered in FTR experiments as water absorbs laser beams at 1064 nm. Fl is intrinsic for many chromophoric active centers in biomolecules, and can obscure the Raman spectrum completely, due to its higher efficiency (up to 10^6 times). Additional source of Fl are traces of impurities in the sample. This problem has seriously restricted routine applications of RS to biomolecules. Tuning λ_{ex} in the near-infrared (NIR) region as well as application of FTR techniques[1,9,14] may overcome this limitation.

In summary, RS in its various forms provides valuable information on the structure of the molecule and its interactions. In particular, certain structural units and chromophoric centers can be probed selectively by exploring the RR approach. In addition, because of the fast response time rapid structural transformations can be followed. Such information is the basis for a long-standing goal of biochemists and biophysicists – to understand the mechanisms of biological phenomena at a molecular level. The structural sensitivity is also extremely attractive for analytical purposes, as it can be used to identify certain biologically active functional groups or biomolecules in different environments and mixtures. A major breakthrough in analytical applications is expected from the combination of RRS and SERS. The possibility of detecting biomolecules at trace level is becoming a reality in universities and research institutes. The development of more reproducible and reliable surface preparation protocols will shift this field to more applied laboratories and clinical units.

The goal of this article to provide orientation on the advantages and limitations of RS, and thus to stimulate the application of this technique to the analysis of biomolecules. We hope to provide an idea of the structural information extractable by different kinds of RS.

Characteristic vibrations and marker bands are the basis of many RS works, and are provided in many sections. It is believed that those bands serve first of all as illustrations in spectra–structure correlations, but can also be used independently in some studies using RS. Selected examples will demonstrate what kind of problems in the analysis of biomolecules can be addressed by RS.

2 HISTORY

The Raman effect was discovered experimentally in 1928 by Raman and Krishnan,[15] and independently by Landsberg and Mandelstam.[16] The importance of the discovery was immediately appreciated by the scientific community, and in 1930 Raman received the Nobel Prize in physics. In 1952, the resonance enhancement effect was observed experimentally by Shorygin.[17] These results were presented in 1953, at a meeting in Gmunden, Austria.[4] In the early, mercury lamp history of RS the biological applications were secondary. Not until 1958 did Garfinkel and Edsall[18] record the first Raman spectrum of a protein, lysozyme. They used a high-pressure mercury lamp for the scattering excitation and photographic plates for the detection. The important step towards a deeper understanding of the structure of proteins came with the determination of the normal vibrational modes of the peptide group in *N*-methylacetamide by Miyazawa et al. in 1958.[19] Further attempts in this direction led to the elucidation of some useful correlations between the amide vibrational spectra and the secondary structure. The discovery of lasers stimulated tremendous growth of Raman applications and in 1968 a report on the first laser-excited Raman spectra of proteins appeared.[20] Two years later Long and Loehr[21] introduced the resonance enhancement effect for the analysis of the

active site of the iron–sulfur protein, rubredoxin. Further application of RRS to biomolecules (heme proteins) led to the discovery of the inverse-scattering polarization phenomenon by Spiro and Strekas[22] in 1972. This discovery stimulated the development of RR theory and had an impact on general RS. The possible use of RS in model membrane studies was first demonstrated in 1971 by Lipperd and Peticolas.[23] At this time several new and powerful Raman techniques emerged. Barron and Buckingham[24] predicted Raman optical activity (ROA) in 1971. Two years later the effect was observed experimentally by Barron et al.[25] An interesting and unpredicted discovery, the SER effect, was observed[26] in an electrochemical cell in 1974. In 1980, after understanding the main features of the effect, first surface-enhanced resonance Raman (SERR) spectra of the adsorbed proteins cytochrome *c* (cyt *c*) and myoglobin (Mb) were reported,[27] at a silver electrode, from solutions containing 10^{-6} M concentrations of proteins. Further development of this technique led to single-molecule detection sensitivity.[10,11]

It is clear from this brief historical overview that biomolecular RS is open for fascinating new discoveries and powerful applications. For example, in 1998 the first ROA spectra from DNA and RNA were reported by Bell et al.[28] opening the new field of direct study of chiral elements in biomolecules.

3 COMPARISON OF RAMAN METHODS

The characteristic mark of modern RS is the variety of techniques used to explore the Raman effect.[9] Table 1 summarizes the main advantages and limitations of methods useful for biomolecular applications.[29–36] To overcome the selectivity and sensitivity limitations characteristic of classical nonresonant RS, the RR and ultraviolet resonance Raman (UV/RR) approaches are extremely powerful. Most importantly, by tuning the λ_{ex} different parts of biomolecules can be selectively probed. This approach will be demonstrated in section 4. SERRS allows adsorbed species to be detected at concentrations in solution of the order of 10^{-10} M. Today this is the most sensitive vibrational technique. However, the price for such sensitivity is the adsorption requirement, which frequently causes denaturation or structural transformations.[33] To preserve the function and structure of biomolecules at surfaces lowering of the temperature or modification of the electrode surface by preadsorbed organic molecules or ions has been suggested.[32,33] In addition, the possibility of photodegradation should be considered seriously in SERRS, SERS, and RR experiments. Various ways of moving or rotating the sample can effectively decrease the destructive influence of the laser beam,[2] and will be considered in more detail. Finally, FTR instruments are very attractive for routine analysis of rather concentrated samples, due to the absence of the Fl problem and their simplicity to use.

4 INTERPRETATION OF RAMAN SPECTRA

Assignment of the bands is the bridge between recorded spectra and normal vibrations of molecules. It is the first step necessary for the application of RS in analysis of biomolecules. The major problem is the complexity of the spectra. In this section we will demonstrate how the combination of several Raman techniques, isotopic substitution, site-directed mutagenesis and depolarization ratio (ρ) measurements is able to considerably simplify the task. Normal-coordinate analysis,[1,2] although a very powerful tool for the assignment of bands, is out of scope of this article and will be not discussed here.

4.1 Combination of Several Raman Techniques

One of the most serious limitations preventing the application of classical vibrational spectroscopy to biomolecules is that the spectra are too complex and overlapped, due to the large number of atoms in the molecule. An elegant solution to this limitation is the application of several Raman techniques to the same sample in combination, providing the possibility of seeing the molecule at different angles. The unique power of combined visible resonance Raman spectroscopy (VIS/RRS) and ultraviolet resonance Raman spectroscopy (UV/RRS) is demonstrated in Figure 1.[31] Electronic absorption transitions from different protein structural units can be observed in the absorption spectrum:

(1) heme charge transfer (CT) band at 600 nm that contains transitions involving the metal ion and the axial ligands;

(2) strong $\pi \rightarrow \pi^*$ Soret transition in heme group at 400 nm;

(3) absorption of aromatic amino acid residues (Trp and Tyr) in the 260–220 nm range;

(4) peptide backbone amide $\pi \rightarrow \pi^*$ transition below 220 nm.

As can be seen from Figure 1, by tuning λ_{ex} from 600 nm to 210 nm it is possible to selectively probe different structural units in the protein:

(1) iron–fluoride (axial ligand) stretches and heme in-plane ring vibrations;

Table 1 Comparison of different Raman methods

Method	Sensitivity and requirements for sample	Advantages	Limitations	Refs.
Nonresonant RS	0.1–0.03 M of nucleotide or peptide group; solid, liquid samples; biomolecules in solutions	Most biological systems can be studied; Fl can be avoided by using red λ_{ex}	Low sensitivity; low selectivity; interpretation difficulties due to complexity of the spectrum from biomolecules	1, 2, 13
Nonresonant RDS	10^{-3} M in protein complexes	Most biological systems can be studied; Fl can be avoided by using red λ_{ex}; probe of ligand–protein, substrate–enzyme, and H-bonding interactions; frequency shift accuracy $\sim$0.1 cm^{-1}; estimation of isotopic frequency shifts; photolabile ligands can be studied	Low sensitivity	29, 30
VIS/RRS	10^{-4}–10^{-7} M of biomolecules	Selective probe of chromophoric groups; high sensitivity	Photodegradation; Fl; chromophore is required; expensive lasers	1, 2
UV/RRS	10^{-3}–10^{-4} M of nucleotide or peptide group; molecules in solution	Selective probe of groups absorbing in 190–300 nm region (peptide group, aromatic amino acid residue, bases of DNA and RNA); high sensitivity; no interference from Fl for $\lambda_{ex} < 260$ nm	Photodegradation; expensive lasers	31
SERS	10^{-4}–10^{-8} M of biomolecules; roughened Ag, Au, Cu surfaces; adsorbed biomolecules	High sensitivity; groups interacting with surface can be probed selectively; adsorption geometry; dependence of the intensity from molecular group on the distance from the electrode; reduction of Fl; excellent ability to study redox behavior of biomolecules in electrochemical cell	Adsorption-induced denaturation; photodegradation; thermodegradation; only adsorbed molecules can be probed	2, 9, 32
SERRS	10^{-6}–10^{-10} M of biomolecules; roughened Ag, Au, Cu surfaces; adsorbed biomolecules	Extremely high sensitivity; selective probe of chromophoric active centers; orientation of chromophores with respect to the electrode surface; intensity dependent on the distance from electrode; reduction of Fl; excellent ability to study redox behavior of biomolecules in electrochemical cell	Adsorption-induced denaturation; photodegradation; thermodegradation; only adsorbed molecules can be probed	9, 32, 33
FTRS	Excitation in NIR region; interferometer	Elimination of Fl; high resolution; excellent spectral subtraction possibilities (can see 1% components); Stokes and anti-Stokes regions can be collected simultaneously (useful for obtaining spectroscopic temperature of the sample); both IR and Raman capabilities in one instrument; ease of use for nonspecialist, safe method, does not required special skills	Low sensitivity; absorption in the NIR spectral region of the analyte; water absorption; overheating problems	2, 9, 14
TR[3]	10^{-3}–10^{-5} M of biomolecules in solution	Picosecond timescale resolution; Raman spectra from excited state molecules; selective probe of chromophoric groups	Photodegradation; expensive lasers	2, 9, 34

(*continued overleaf*)

Table 1 (*continued*)

Method	Sensitivity and requirements for sample	Advantages	Limitations	Refs.
MRS	Biomolecules in films; biomolecules adsorbed at surfaces of (combined with SERS); sensitivity depends on combination with RR or SERS/SERRS	Spatial resolution 0.1–2 μm; low sample mass (picogram range)	Photodegradation	2, 9, 12, 35
ROA	0.1–0.01 M of nucleotide or peptide group; biomolecules in solution	Sensitive to 3-D structure (or tertiary fold in the case of proteins) of chiral molecules and molecular groups	Low sensitivity; high acquisition times	9, 36

RDS, Raman difference spectroscopy; VIS/RRS, visible resonance Raman spectroscopy; UV/RRS, ultraviolet resonance Raman spectroscopy; FTRS, Fourier transform Raman spectroscopy; TR^3, time-resolved resonance Raman; IR, infrared; 3-D, three-dimensional.

Figure 1 Selective probe of different structural units of sperm whale Mb by RRS: (a) absorption spectrum; (b) ultraviolet (UV) excitation at ~225 nm enhances tyrosine (Tyr) and tryptophan (Trp) bands (structures shown); (c) excitation further in the UV region enhances amide vibrations whose intensities and frequencies depend on the protein secondary structure (structure of amide group shown). Excitation within the heme absorption bands in the visible spectral region (400–600 nm) enhances vibrations only of (d) the heme ring (structure shown) and (e) vibrations between the heme iron and its axial ligands. No protein vibrational modes are observed. [Reproduced by permission of American Chemical Society from S.A. Asher, *Anal. Chem.*, **65**(4), 201A–210A (1993).]

(2) heme in-plane ring vibrations;

(3) vibrations of aromatic rings in Trp and Tyr;

(4) amide backbone vibrations.

Detailed information on the binding of the ligand to the metal ion, the spin and redox states of the heme group, the state of Tyr and Trp residues, and the secondary structure of the protein can be collected from such investigations.

The second promising combination is used for studies of adsorbed biomolecules. It is straightforward to apply both SERRS and SERS techniques to molecules containing chromophoric groups, by changing λ_{ex}. As has been demonstrated[33] details on the state of the heme group (chromophore) can be derived from SERRS studies of the adsorbed protein cyt *c*, while information on coadsorbed anions, the state of amino acid residues close to the surface, or groups possibly involved in binding to the surface, can be extracted from SERS.[37] It is important to note that the state of the heme, which is probed by SERRS, in many cases is determined by the interactions of the protein with the surface or with adsorbed ions, which are probed by SERS. Thus complete and unique information on the metal/protein interface can be collected.

4.2 Isotopic Substitution

Vibrational frequencies are determined by the force field and masses of the atoms. Isotopic substitution selectively affects the mass of the vibrating atoms at a particular place in the molecule, but in general does not influence the bonding properties between atoms. Consequently, isotopic exchange of atoms is reflected in the frequencies as isotopic shift (Δ). Isotopic substitution plays a key role in solving the following problems:

(1) assignment of the vibration of a particular molecular group in the spectrum;

(2) coupling between vibrations;

(3) identification of the ligand and its binding mode (for example, it is possible to determine the number of identically bonded atoms using isotopically labeled ligand atoms).

As interpretation of the vibrational spectrum is one of the major problems in biospectroscopy, direct assignment of the vibrations of particular molecular groups in the spectrum through isotopic substitution is an indispensable tool in RS. The largest Δ is observed when H is replaced by D. The simplest way to produce such an exchange in biomolecules is by using D_2O as a solvent. The hydrogen atoms attached to N, O, and S atoms are mobile and will spontaneously exchange with deuterium provided these groups have sufficient accessibility to the solvent. The frequency ratio can be evaluated by using Equation (1) for two atom molecules:

$$\nu(m_1m_2) = \frac{1}{2\pi}\sqrt{k\left(\frac{m_1+m_2}{m_1m_2}\right)} = \frac{1}{2\pi}\sqrt{\frac{k}{\mu}} \qquad (1)$$

where m_1 and m_2 are the masses of the atoms, k is the force constant, and μ is the reduced mass. The calculation for the particular ν(NH)/ν(ND) case is shown in Equation (2).

$$\frac{\nu(\mathrm{NH})}{\nu(\mathrm{ND})} = \frac{\sqrt{(14+1)/(14\times 1)}}{\sqrt{(14+2)/(14\times 2)}} \approx 1.37 \qquad (2)$$

This means that the stretching vibration of the N–H bond, for example in the amine group of the lysine amino acid residue, will shift from $\sim$3300 cm^{-1} to $\sim$2360 cm^{-1}. From Table 3 in section 6.1, we can see that such a shift is indeed observed and helps to assign vibration of this group in the spectra. Coupling between vibrations arises when atoms of similar masses are connected in the molecular group by similar strength bonds.[2] For example, separate stretching vibrations of N–H, C–C, or C–O bonds cannot be found in the $-NH-CH_2-CH_2-O-$ group. Isotopic exchange of $^{14}N/^{15}N$ in this molecular group would lead to shifts in positions of several bands, thus indicating those vibrational modes and how much they are coupled with the motion of the N atom. The extent of the coupling can be recognized roughly from the Δ value (the stronger the coupling, the larger the Δ value). An interesting example is coupling between ring vibrational modes with N–H deformation in the imidazole ring of histidine (His). As shown in section 6.1, perturbations in coupling between vibrations induced by the replacement of the N–H group by the N–D group in acidic D_2O solutions result in completely different Raman spectra, featuring a very strong peak at 1408 cm^{-1}. This band from the protonated imidazole ring in D_2O solutions serves as the best His residue marker band for analytical purposes. Blue copper proteins are the other important examples of vibrational coupling. As shown in section 6.2, the isotopic $^{32}S/^{34}S$ and $^{14}N/^{15}N$ substitutions in the molecular group $Cu-S-C_\beta-C_\alpha-N$ induce clear shifts in all the observed low-frequency RR modes, showing that all the bands are generated by the ν(Cu–S) stretching vibration coupled with the deformations of the $Cu-S-C_\beta-C_\alpha-N$ moiety. In studying coupling phenomena, isotopic substitution experiments combined with normal coordinate analysis[1,2] are the most powerful tools.

Figure 2 demonstrates how isotopic substitution helps to understand protein–ligand bonding in cytochrome *bd*

Figure 2 Identification of a ferryl intermediate in cytochrome *bd* oxidase. [Reproduced by permission of ACS from T.M. Loehr, ACS Symposium Series 692, eds. E.I. Solomon, K.O. Hodgson, ACS, Washington, 136–153, 1998.]

oxidase.[38] The reduced enzyme interacts with O_2 and the nature of the formed species was identified by RRS. In Figure 2 the ferryl intermediate Fe(IV)=O was identified using $^{18}O_2$, $^{16}O_2$ and mixed-isotope $^{18}O^{16}O$ dioxygen species. As can be seen, the position of one band clearly depends on the O_2 isotope used, and shifts from 815 cm^{-1} to 769 cm^{-1} upon $^{16}O_2 \rightarrow {}^{18}O_2$ substitution. The intensity of the peaks remains unchanged. In this frequency range two vibrational modes are expected: ν(O–O) from Fe–O–O^- species or ν(Fe=O) from Fe(IV)=O species. Unambiguous identification of Fe(IV)=O comes from the third experiment, using mixed-isotope $^{18}O^{16}O$ species. The vibrational modes $\nu(^{18}O-{}^{18}O)$, $\nu(^{16}O-{}^{16}O)$, and $\nu(^{16}O-{}^{18}O)$, should have different frequencies; thus if Fe–O–O^- species are present a new band should appear in the $^{16}O^{18}O$ experiment midway ($\sim$792 cm^{-1}) between the bands observed in the $^{16}O_2$ and $^{18}O_2$ experiments. Because no peak was observed in the vicinity of 790 cm^{-1}, the assignment of the observed bands to the ν(Fe=O) vibrations is definitive.

4.3 Mutation

Replacement of the entire amino acid residue in a protein through mutation combined with RS opens a way to study

(1) properties of individual amino acid residues[29]
(2) effects of mutation on protein structure[29]
(3) architecture and spectroscopy of the active centers in proteins.[39]

The ionization state of carboxyl groups has been monitored by comparing nonresonant Raman difference spectra of the wild-type protein and a mutant in which the carboxyl group was replaced by serine.[29] New insights into the spectroscopy of the active site of the blue copper protein, azurin (Az) have been revealed by the mutation of the His ligand to glycine (Gly).[39] In the active site of Az, the Cu ion is strongly coordinated by three ligands: one S atom from the cysteine (Cys) residue, and two N atoms from imidazole rings of His residues. The problem lies in deciding which of the bands in multiple RR spectra correspond to the Cu–N vibration. It was shown that mutant Az is able to bind exogenous ligands.[39] This approach opens the way to constructing an active site in which the Cu ion coordinates ^{15}N-labeled imidazole, simply by introducing isotopically labeled imidazole in the solution containing mutated protein. No isotope dependence was observed in the RR spectra of Az mutant reconstituted with ^{15}N-imidazole, indicating that His ligands do not contribute significantly to the spectrum of Az.

4.4 Depolarization Ratio Measurements

The depolarization ratio (ρ) is defined as shown in Equation (3)

$$\rho = \frac{I_\perp}{I_\parallel} \tag{3}$$

where $I_\perp$ and $I_\parallel$ refer to the intensities of scattered radiation polarized perpendicular and parallel to the incident light, respectively. Such measurements can be performed very easily for biomolecules in solution by placing the analyzer in the path of scattered Raman light between the sample and slit. Two spectra must be collected at perpendicular and parallel rotations of the analyzer. Thus ρ can be estimated for each band in the spectra. Important information about the symmetry of vibrational modes, which is critical in performing assignments of the bands, can be extracted from the ρ value

- $0 < \rho < 3/4$ for totally symmetric (polarized) vibrations
- $\rho = 3/4$ for nontotally symmetric (depolarized) vibrations

- $3/4 < \rho < \infty$ for anomalous (inverse) polarized vibrations (can only be observed in RR spectra).

The phenomenon of anomalous polarization was discovered in studies of heme proteins, hemoglobin and cyt *c*.[22] Polarization measurements were critical in making assignments in the RR spectra of complex heme proteins. Totally symmetric (A_{1g}), nontotally symmetric (B_{1g} and B_{2g}) and anomalously polarized (A_{2g}) bands were distinguished.

5 EXPERIMENTAL

The classical Raman spectrometer consists of the following main components:

(1) excitation source (laser);
(2) sample illumination;
(3) sample holder;
(4) scattered radiation collection system;
(5) monochromator or spectrograph;
(6) detection system [photomultiplier or charge-coupled device (CCD) camera].

The focus in this section will be on sampling schemes, avoiding laser effects on the integrity of the biomolecules, and calibration of the spectrometer.

5.1 Sample Handling

Laser-induced photodegradation of the sample is a major concern in RRS, UV/RRS, SERS, and SERRS experiments (Table 1). The principal solution used to avoid this effect is based on moving the laser spot relative to the sample. Such a procedure decreases the illumination time per sample volume or area. Rotating liquid sample cells,[40] liquid samples flowing through capillaries, rotating electrodes,[41] moving electrochemical cells,[42] and scanning beam techniques[43] have been developed. Some of them are shown in Figure 3.

5.2 Frequency and Intensity Calibration

Various methods[44–46] used for frequency calibration are compared in Table 2. The best accuracy can be achieved using neon emission lines. This method works very well for both one-channel detection systems (using photomultipliers) and multichannel detectors.[44] The small red commercial pilot lamp is easily available. It is convenient to record Ne lines and Raman spectra of the sample simultaneously. After the calibration Ne lines can be subtracted using the reference spectrum recorded with a blocked laser beam. An extensive list of Ne emission lines is available[44] in the wavelength range from 313 nm to 890 nm. As the Ne line method is an absolute wavenumber method, the exact λ_{ex} is required

Figure 3 Sample schemes employed to avoid laser-induced photodegradation of the sample: (a) flowing capillary cell for liquids; (b) rotating cylindrical electrode for liquids; (c) rotating cylindrical electrode with use of cylindrical lens for surface Raman studies; (d) moving electrochemical cell for surface Raman studies. Raman Spectrosc.*, **19**, 65–69 (1988); (d) reproduced by permission of John Wiley & Sons from G. Niaura, A.K. Gaigalas, V.L. Vilker, *J. Raman Spectrosc.*, **28**, 1009–1011 (1997).]

Table 2 Comparison of methods for frequency calibration[a]

Method	Accuracy (cm^{-1})	Advantages	Limitations
Internal standard (solvent bands or specially added compounds)	1	Simplicity; determined frequencies are temperature-independent; intense bands of tetrahedral anions may be used in aqueous solutions: SO_4^{2-} $\nu_s = 981\,cm^{-1}$; ClO_4^- $\nu_s = 935\,cm^{-1}$	Low accuracy; possible interaction of biomolecules with standard; narrow frequency range
Indene (Raman shift standard)	0.5	High accuracy; independent of λ_{ex} (useful for dye lasers)	Cannot be measured simultaneously with the sample; not useful for the high-frequency Raman calibrations ($1800-2700\,cm^{-1}$)
Laser plasma lines	<1	High accuracy; high density of lines; wide frequency range	Limited by the laser used
Neon emission lines (absolute wavenumber standard)	0.2	Very high accuracy; wide frequency range; best for multichannel detectors; possible simultaneous recording with the sample spectra	Accurate λ_{ex} value required (for dye lasers λ_{ex} must be determined)

[a] Based on Ferraro and Nakamoto,[2] Laserna,[9] Hamaguchi,[44] Strommen and Nakamoto,[45] and Fryling et al.[46]

for recalculating the positions of the lines to the Raman shifts. If the precise λ_{ex} is not known (for instance when working with dye lasers) it should be also calibrated against the Ne lines. The exact λ_{ex} value is not required for Raman shift methods, because of the well-known peak positions of standard samples. A spectrum from indene, which is recommended by the International Union of Pure and Applied Chemistry (IUPAC) for frequency calibration, is shown in Figure 4. Indene should be purified before use by vacuum distillation.[2]

Intensity calibration is a complicated issue in RS. Two aspects of the problem are considered in this section: estimation of the analyte concentration based on the intensity of the particular Raman band, and calibration of spectrometer sensitivity with respect to the wavelength (correction of relative intensities in the spectra). The intensity of the Raman scattering of a particular vibrational mode from the analyte molecule (I_a) depends on many factors,[2,45] as shown in Equation (4):

$$I_a = I_0 \nu^4 K(\nu) A(\nu) \beta_a C_a \tag{4}$$

where I_0 is the intensity of the incident laser radiation, ν is the Raman frequency, $K(\nu)$ is the overall spectrometer response, $A(\nu)$ is the self-absorption of the medium (important for RR studies), β_a is the molar Raman scattering parameter of the analyte molecules, and C_a is the concentration of the analyte molecules. Because the parameters $K(\nu)$, $A(\nu)$, and β_a are difficult to evaluate, relative rather than absolute intensities are employed in RS for C_a determination. For this purpose many internal intensity standards may be used, such as the tetrahedral anions ClO_4^- ($935\,cm^{-1}$ band) and SO_4^{2-} ($981\,cm^{-1}$ band), or water bands ($\delta(HOH) = 1640\,cm^{-1}$, $\nu(OH) = 3400\,cm^{-1}$, and $\delta(DOD) = 1204\,cm^{-1}$, and $\nu(OD) = 2500\,cm^{-1}$). If parameters referring to internal standard molecules are denoted by $K(\nu')$, $A(\nu')$, β_s, and C_s, the relative intensity $I_a(rel) = I_a/I_s$ can be expressed as shown in Equation (5):

$$I_a(rel) = \frac{\nu^4 K(\nu) A(\nu) \beta_a C_a}{(\nu')^4 K(\nu') A(\nu') \beta_s C_s} = \text{constant} \times C_a \tag{5}$$

The value of the constant may be determined easily by introducing a known amount of the analyte C_a(known). The calibration curves of Raman intensity versus concentration are linear.[1]

Several methods have been proposed for the correction of spectrometer response with wavelength:

(1) tungsten lamps;[45,46]
(2) standard lamps from the National Institute of Standards and Technology (NIST);
(3) pure rotational spectrum from D_2;[44]
(4) Fl spectrum from quinine.[44]

The discreteness of the lines and narrow frequency range limit the application of the rotational Raman spectrum from D_2. The Fl method suffers from a rather narrow spectral range (400–600 nm) and the requirement to use a UV laser for the excitation of the radiation. The combination of a tungsten lamp and fiber optics was demonstrated[46] to be a promising choice as the white light source for intensity calibrations (Figure 5). For the Raman intensity correction to the instrument response, the measured Raman spectrum should be divided by the white spectrum recorded from the tungsten lamp at the same experimental conditions.[46]

6 APPLICATIONS TO BIOMOLECULES

This section will describe the applications of various kinds of RS to biological systems. Starting from the spectroscopic characterization of simple structural elements using marker bands, we will show how this knowledge can be applied to the molecular-level characterization of more diverse biological systems. The emphasis will be on the spectrum–structure correlations provided in the numerous tables.

Applications of RS to biomolecular studies are rapidly increasing. A number of excellent reviews have been published concerning studies of peptides,[47–51] active centers of proteins,[52–59] nucleic acids,[60–62] membranes,[63–66] dynamics of biomolecules,[67–69] and microscopic applications.[70]

6.1 Amino Acids and Peptides

Amino acids are the fundamental building blocks of proteins and therefore attract much attention from vibrational spectroscopists. The Raman technique was first applied to amino acids by Garfinkel and Edsall in 1958.[71] From then on these systems have been extensively studied by nonresonance Raman,[47,72–78] UV/RR,[48,49,79] ROA,[36] and SERS.[32] The information obtained in such studies can be divided into three categories: identification, structural and conformational analysis, and interactions.

Precise identification of amino acid residues in proteins is a difficult task even for such a structure-sensitive technique as RS. This is because many functional groups present in proteins contribute to the spectra, and as a result the observed bands are broad and overlap. To overcome these difficulties a combination of several approaches is very useful. We will concentrate on three of them:

(1) isotopic solution H_2O/D_2O exchange
(2) variation of pH
(3) application of the UV/RR technique.

The usefulness of such an approach can be seen from Table 3, where characteristic vibrations of the main functional groups of amino acids in different environments are summarized. The frequencies of the vibrations of N–H, O–H or S–H bonds containing exchangeable hydrogen atoms are lowered by a factor of approximately $\sqrt{2}$ going from H_2O to D_2O solutions. Such a big shift in principle allows identification of the amine ($-NH_2$), ammonium ($-NH_3^+$) and sulfhydryl ($-SH$) groups (Table 3). For example, the sulfhydryl group can be immediately identified by the observation of the strong band in the 2560–2580 cm^{-1} region in H_2O solutions, which shifts to 1850–1880 cm^{-1} in D_2O. However, $\nu_s(NH_2)$ falls in the region of strong water scattering, and subtraction of a pure water spectrum is recommended. It should be noted also that full width at half-maximum (fwhm) for the N–H vibration in an $-NH_2$ group is considerably lower than vibrations of water. More serious problems are related to identification of the ammonium group. A high rate of exchange of protons and extended H-bonding interactions result in very high fwhm for these bands in addition to their

low intensity. In this situation the combined analysis of $\delta_s(NH_3^+)/\delta_s(ND_3^+)$ vibrations (Table 3) might be helpful. It is not only direct vibrations of the bond involving hydrogen atoms that can be probed by the H_2O/D_2O exchange approach. For example, some bands from the indole ring of Trp residue and the imidazole ring from His residue clearly shift on deuteration (Table 3).[73–75] The effect is associated with the coupling of certain ring vibrations with deformational N–H motion. In the case of the Trp residue two strong features at 759 and 1012 cm^{-1} can serve as the marker bands, and a slight shift of the first band to 754 cm^{-1} in D_2O solutions can serve as a reliable confirmation of the assignment, but the analysis of His residues strongly requires isotopic addition experiments. Three main phenomena control the shape and structure of the vibrational spectrum of the imidazole ring in His, depending on environmental conditions:

(1) extensive coupling of ring vibrational modes with N–H deformation;
(2) increases in local symmetry from C_s to C_{2v} upon protonation of both N atoms in the imidazole ring (as a result the spectrum is considerably simplified);[75]
(3) tautomerism of the neutral imidazole ring[73] (Table 3).

The protonated, positively charged imidazolium ring can be undoubtedly identified by the strong and narrow band at 1408 cm^{-1} which appears in D_2O solutions (Table 3). This band clearly dominates in the spectrum and serves as the best spectral signature for His residues. The symmetric stretching vibration $\nu_s(COO)$ from carboxylate groups and the deformational motion $\delta(CH_2)$ from methylene groups are possible interferences, although those bands do not change position in H_2O and D_2O solutions. Monitoring of the imidazole ring pK_a is the second valuable application of the 1408 cm^{-1} feature. On the other hand, tautomerism should be investigated in H_2O solutions by using the three tautomer-sensitive bands indicated in Table 3. There are also three bands sensitive to the ionization state of the imidazole group in H_2O solutions, located at 1627, 1484, 1193 cm^{-1} and 1568, 1440, 1160 cm^{-1} in protonated and deprotonated forms of the imidazole ring, respectively. Successful use of these bands for pK_a evaluation of His residues in proteins by employing RDS has been demonstrated by Yue et al.[78] Next, the advantages of UV/RRS for analysis of amino acids will be considered. Four aromatic amino acids, Phe (phenylalanine), Tyr, Trp and His, containing electronic transitions in the 190–300 nm wavelength region (Table 4) can be studied by the RR technique, which explores 10–1000-fold enhancement in intensity of the Raman bands due to the resonance effect.[31,79,80] By choosing an appropriate λ_{ex} it is possible to selectively probe particular amino acid residues in the protein, since to a very rough approximation the resonance enhancement is proportional to ε^2.[38] For example, Trp and Tyr can be examined selectively using λ_{ex} at 218 and 200 nm respectively (Table 4).

The second most important structural element in proteins is the peptide bond, which connects together amino acids. Thus in proteins not only are vibrations characteristic of individual amino acid residues observed, but also additional bands associated with particular peptide bonds (Figure 6). Normal vibrational modes of peptide groups were first determined by Miyazawa et al.[19] in 1958 using the model compound *N*-methylacetamide. Further experimental and theoretical efforts in this field led to the elucidation of important correlations between the amide vibrational spectra and the secondary structure of proteins.[47,50,51] Recent advances in this field are associated with the application of resonance enhancement of the amide vibrations using λ_{ex} in the UV region.[48,49]

Three in-plane vibrations of the peptide group are important in Raman studies: amide I, amide II and amide III (Figure 6). In D_2O solutions, exchange of hydrogen with deuterium takes place and the corresponding amide vibrations are labeled as amide I′, amide II′, and amide III′. As can be seen from Figure 6, the amide I vibration is concentrated on the motion of the C=O

group, while the other two modes have higher contributions from the in-plane bending of N–H, and therefore can be easily detected by their considerable frequency reduction in D_2O solutions. The amide II mode, usually very weak in nonresonant RS, appears as an intense band in UV/RRS, especially in D_2O solutions. The high contribution from the stretching C–N vibration results in the considerable resonance enhancement of this special vibration. Particular enhancement of the amide II′ mode comes from the transformation of this vibration to the ν(CN) mode upon H→D exchange. The H-bonding between the hydrogen of the NH group and the oxygen of the CO group (Figure 6) is an essential component in determining the secondary structure of proteins. The H-bonding strength and rotation reflect on the amide frequencies. Thus different protein structures can be distinguished based on these frequencies, as shown in Figure 7. The frequency ranges presented demonstrate the basic trends in spectrum–structure correlations, although in each particular case such correlations should be considered with some caution.[50] A selective probe of amide vibrations is possible through the UV/RR approach with $\lambda_{ex} < 220$ nm. The electronic absorption spectrum of the peptide group is characterized by three transitions:[49] weak $n \rightarrow \pi^*$ at 220 nm; strong $\pi \rightarrow \pi^*$ at 190 nm; and $n \rightarrow \sigma^*$ at 165 nm. Excitation within the $\pi \rightarrow \pi^*$ transition enhances vibrational modes significantly coupled to ν(C–N), i.e. amide II and III vibrations (Figure 6). Excitation within the $n \rightarrow \sigma^*$ absorption selectively enhances the amide I mode.[49] A selective probe of amide bands in Mb with $\lambda_{ex} < 220$ nm is shown clearly in Figure 1.

6.2 Active Centers in Proteins

Active centers in proteins are mainly responsible for the particular biological function of the biomolecule.

Figure 7 Correlation between amide I and III wavenumbers and protein conformations. There are always exceptions in band wavenumbers, but the ranges shown in the figure usually cover the majority of bands for a given conformation. [Reproduced by permission of John Wiley & Sons from A.T. Tu, in *Spectroscopy of Biological Molecules*, eds. R.J. Clark, R.E. Hester, John Wiley & Sons, Chichester, 47–112, 1986.]

In metalloproteins, metal ions coordinated by protein amino acid residues or certain molecular groups serve as a catalytic center of enzyme action or are involved in the electron transfer process. In many cases such active centers are chromophores and thus can be studied selectively by the RR technique. Unique information on the structure and dynamics of active centers can be extracted from the vibrational spectra. In this section, selected examples are used to illustrate applications of RRS to metalloproteins.

Heme proteins are the classical examples used in RR studies, because of their important biological functions and the possibility of observing high-quality spectra even in dilute solutions. Indeed, the first biomolecular application of RRS was performed on heme proteins by Spiro and Strekas in 1972.[22] The heme group, which consists of the porphyrin ring system and a coordinately bound iron ion (see structure in Figure 1), has intense electronic π–π^* absorption bands, because of the extended π system of the porphyrin ring. The main features of the heme electronic spectrum can be summarized as follows:[54]

- an intense band near 400 nm (Soret or B band, $\varepsilon \approx 10^5\ M^{-1}cm^{-1}$);

- a pair of peaks (about ten times weaker) at ~520 and ~550 nm (β and α or Q_v and Q_0 bands respectively);
- weak CT transitions.

Because coordination of nitrogen atoms from the porphyrin ring to the central metal ion influences the structure of the macrocycle, the observed resonance-enhanced vibrational spectrum contains unique information on the state of the central ion. Vibrations of axial ligands such as CO, CN^-, O_2, F^-, OH^- and NO can also be studied due to coupling with electronic $\pi-\pi^*$ transitions.[52,53] Excitation within CT transition also results in enhancement of the axial ligand modes.[52] The heme group can be considered in the first approximation as a planar structure with D_{4h} symmetry. Further, if the substitutents are treated as point masses, the in-plane and out-of-plane vibrational modes can be represented according to the symmetry shown in Equations (6) and (7), respectively.[54]

$$\Gamma_{\text{in-plane}} = 9A_{1g} + 8A_{2g} + 9B_{1g} + 9B_{2g} + 18E_u \quad (6)$$

$$\Gamma_{\text{out-of-plane}} = 3A_{1u} + 6A_{2u} + 5B_{1u} + 4B_{2u} + 8E_g \quad (7)$$

Because of the presence of the center of symmetry in an idealized heme group, the mutual exclusion principle operates for the Raman and IR selection rules. Only the ''gerade'' (g) modes are Raman-active, while ''ungerade'' (u) modes are IR-active. The allowed Raman modes can be recognized in the spectra by different polarization properties: A_{1g} modes are polarized, B_{1g} and B_{2g} modes are depolarized, and A_{2g} modes are anomalously polarized. It should be noted that the phenomenon of ''anomalous polarization'' was first observed by Spiro and Strekas for the heme proteins hemoglobin and cyt *c*.[22] The observed spectral pattern depends on λ_{ex}. There is a relationship between the symmetry of resonantly enhanced vibrational modes and the nature of the electronic transition. For a single molecule the Raman intensity I_R is given by Equation (8)

$$I_R \sim I_0 \nu_R^4 \sum_{p,\sigma} (\alpha_{p\sigma})_k^{\ 2} \quad (8)$$

where I_0 is the intensity of incident light, ν_R is the Raman wavenumber, and $(\alpha_{p\sigma})_k$ is the polarizability tensor component for the k transition. The summation is over molecular coordinates p and σ. For RR scattering, in the first approximation the polarizability tensor can be described by two terms as shown in Equation (9).

$$(\alpha_{p\sigma})_k \approx A + B \quad (9)$$

Depending on the nature of the electronic transition, term *A* or *B* dominates. The main features of terms *A* and *B* can be summarized as follows.

- Term *A* is associated with vibrational interactions with the excited electronic state through Franck–Condon overlapping and usually is a leading contributor to RR intensity. Fundamentals, overtones and combination bands of totally symmetric modes dominate in the spectra. For the heme group this resembles excitation within the B band and resonance enhancement of A_{1g} modes and overtones.
- Term *B* is associated with the vibronic coupling of one resonantly excited state to another excited state. As a result, fundamental transitions of nontotally symmetric vibrations are resonantly enhanced. This is often the case when excitation is within a weakly allowed electronic transition which is vibronically coupled with a strong electronic transition. For the heme group this resembles excitation within Q bands and resonant enhancement of B_{1g}, B_{2g} and A_{2g} modes.

Thus by choosing the appropriate λ_{ex}, the A_{1g} or B_{1g}, B_{2g} and A_{2g} modes can be investigated separately, considerably simplifying the interpretation. In real biological systems the symmetry of the heme group is distorted from the idealized D_{4h} as a result of asymmetric substitutions and deformation of the planar heme structure due to interactions with the protein matrix. Indeed, many in-plane IR-active E_u and out-of-plane deformation modes have been observed in cyt *c* RR spectra due to the protein-induced distortion of the heme group.[81] When assignment of the RR spectrum is performed, unique information on the state of the heme metal ion can

Figure 8 Overview of RR spectrum of the substrate-free ferric cytochrome P-450 LM2 [$(LM2)^{ox}$] excited at 407 nm. [Reproduced by permission of Akademie Verlag from P. be derived by analyzing certain marker bands. A typical RR spectrum from a heme group excited within the B electronic band is presented in Figure 8. Totally symmetric A_{1g} vibrations dominate in this spectrum. Representative marker bands at different states of the heme iron ion are summarized in Table 5. Three main reasons are responsible for the sensitivity of the high-frequency in-plane stretching modes to the state of the Fe ion.[56]

- The frequency of the C–N and C–C stretching vibrations of the heme group depends on the electron density on the antibonding π^* orbitals of the porphyrin ring. Higher electron density weakens the order of C–C and C–N bonds, and as a result the frequency decreases. Transition from Fe^{3+} to Fe^{2+} increases electron occupation on π^* orbitals and can be recognized by the lowering of frequency (Table 5). On the other hand, all chemical effects causing withdrawal of the electrons from π^* orbitals cause increases in frequency. Such effects refer to the axial ligation of the π acid ligands as CO, NO and O_2.
- Stretching frequencies of the porphyrin ring depend on the core size of the porphyrin cavity. The core size depends on two factors: the spin state of the Fe ion, and the coordination number (CN). In the high-spin (HS) state two antibonding d orbitals of the Fe ion contain an electron and the porphyrin ring cavity is expanded compared with the low-spin (LS) state, where the antibonding d orbitals are empty. Expanding the core size decreases stretching frequencies (Table 5). The CN of the central Fe ion influences the core size as follows: in the 6C state the Fe ion is located in the heme plane, while in the 5C state the central ion is dislocated from the heme plane towards the fifth ligand. Such a dislocation decreases the core size and as a result, stretching frequencies increase (Table 5).
- Twisting and tilting of Pyr rings in the heme group form the idealized plane structure induced by the protein matrix.[56,81]

The axial ligation of the heme group can be studied not only through the high-frequency stretching vibrations of the porphyrin ring, but also directly by analyzing the stretching $\nu(M-AB)$, bending $\delta(M-A-B)$ and internal $\nu(A-B)$ modes (Figure 9) of two atomic AB ligands bonded with the metal ion M. Such modes were observed in RR spectra excited within the B electronic transition.[52,53] Important structural information about the bonded AB ligand, including the angle $M-A-B$ and the strength of the $M-A$ bond, can be derived from such studies.[52,53]

The RR spectra of heme proteins can be observed because of $\pi-\pi^*$ electronic transitions in the porphyrin

Figure 9 Schematic representation of metal–ligand (a) stretching, (b) bending and (c) internal ligand vibrations in the complex formed between CO and the iron ion of the heme group. Data for (c) from Yu and Kerr.[53] [(a) and (b) reproduced by permission of Academic Press from N.-T. Yu, *Methods Enzym.*, **130**, 350–409 (1986).]

Figure 10 Overview of low-frequency RR spectra of blue copper protein Az (1 mM) from *Pseudomonas aeruginosa* obtained with 647 nm excitation. Integration time, 200 s. Insert shows the active site structure; bond lengths indicated in Å. (Data for insert from Nar et al.[82])

system. A different resonance enhancement mechanism in the Raman spectra operates for other metalloproteins, where the metal ion is directly ligated to the protein amino acid residues. Interesting examples for vibrational spectroscopy are the ''blue copper'' proteins (plastocyanin, Az, stellacyanin and others). The biological function of these proteins, electron transport, is closely related to the geometry of the active site. The structure of the Cu active center in Az can be described as trigonal-bipyramidal (Figure 10). Three strongly bonded ligands, namely the S atom of Cys, and two N imidazole ring atoms from His groups, are arranged in planar trigonal configuration. Two weakly bonded ligands, the S atom from methionine and the O atom from the peptide carbonyl of Gly, lie in the axial position with respect to the trigonal plane.[82] The axial ligands turn the geometry from trigonal to trigonal-bipyramidal. Such a structure is a compromise between the tetragonal geometry usually observed for Cu(II) coordination compounds, and the tetrahedral arrangement characteristic of the Cu(I) compounds, and is believed to be responsible for the fast electron-transfer rates typical for blue copper proteins. In the Cu(II) oxidation state these biomolecules exhibit intense electronic absorption bands around 600 nm assigned to the electronic $S(Cys)(\pi) \rightarrow Cu(II)(d_{x^2-y^2})$ CT transition. The RR spectrum produced by the excitation within this transition consists of several intense bands in the low frequency region (200–500 cm^{-1}), where metal–ligand vibrational modes are expected (Figure 10). Because the electronic transition involves CT from the S(Cys) to Cu(II) ion, the Cu–S bond properties are considerably affected by the absorption, and resonant enhancement in the Raman spectrum is concentrated on vibrations of the Cu–S bond. However, not one but several clear bands are observed experimentally. The origin of the bands has been discussed extensively.[56,58,83,84] In the earlier studies these bands were attributed to vibrations of Cu–N and Cu–S bonds.[83] Later, strong coupling between stretching ν(Cu–S) and deformation δ(SCC) vibrations from the Cys moiety was suggested to explain the observed lower isotopic $^{63}Cu \rightarrow {}^{65}Cu$ frequency shift in stellacyanin compared with the value predicted by normal coordinate analysis.[84] Recent extensive isotopic substitution experiments[39,56,58] (Table 6) provide evidence that all the bands observed in the 200–500 cm^{-1} frequency range are generated by stretching vibrations of the Cu–S(Cys) bond dramatically coupled with deformations of the $Cu-S-C_\beta-C_\alpha-N$ moiety. Multiple shifts induced by all $^{14}N \rightarrow {}^{15}N$ substitutions demonstrate the participation of the remote N atom of the Cys linkage

in the coupling phenomenon (Table 6), because no isotopic shifts were observed with labeled N atoms of the imidazole ring in mutant Az.[39] Experiments with engineered active sites in mutant Az proteins[85] revealed the sensitivity of the ν(Cu–S) frequency to the length of the Cu–S(Cys) bond and thus to the geometry of the active center. The highest frequency, in the vicinity of 430–405 cm^{-1}, corresponds to the trigonal coordination (Figure 11). Weak axial interactions by the L' ligand cause a slight reduction in frequency. As bonding between the Cu ion and the L' ligand becomes stronger, and the geometry of the active sites changes through tetrahedral to tetragonal, the ν(Cu–S) frequency undergoes a further reduction to 320–300 cm^{-1} in the pure tetragonal arrangement. As happens frequently with Raman studies of biological molecules, the extended coupling observed between vibrational modes and ν(Cu–S) frequency–structure correlations goes far beyond the problems of blue copper proteins and has an impact on the vibrational spectroscopy of coordinated compounds in general.

Figure 11 Correlation between coordination geometries in mononuclear copper cysteinate proteins and frequencies of Cu–S(Cys) bond stretching vibrations. Res.*, **29**(8), 365–372 (1996).]

6.3 Nucleic Acids

Applications of RS for the analysis of nucleic acids have been increasing rapidly since the pioneering work of Lord and Thomas in 1967.[86] Excellent reviews of this extremely complex field are available.[60–62] Several different and powerful Raman techniques, such as nonresonant RS,[60–62] UV/RR,[49,87] RDS,[88] SERS,[32] and ROA,[28] have been applied in this field, providing different structural flavors for these biomolecules. Excitation in the UV region holds several advantages.[87]

(1) The overall spectrum is simplified, because only the vibrational modes from heterocyclic components of nucleic acids (purine and pyrimidine bases) are preferentially enhanced.

(2) The relative intensity of bases depends on λ_{ex}, and thus monitoring of particular bases becomes possible. For example, the guanine (G) and adenine (A) residues can be followed selectively using excitation at 250 and 240 nm.[87]

(3) Some modes (for example the $\delta(NH_2)$ mode which is important in H-bonding studies) which are heavily overlapped with conventional excitation can be observed using the UV/RR approach.[87]

Recently, a powerful new Raman technique called vibrational ROA was introduced in the field of nucleic acid studies by Bell et al.[28] The ability of the technique to provide new structural information on conformations of the sugar ring and phosphate backbone has been demonstrated.

The large number of Raman studies on native nucleic acids as well as on model compounds has led to the identification of certain marker bands whose frequency or intensity are sensitive to the structure. In this section we will show what kind of information about nucleic acids can be extracted from the Raman approach. We will try to briefly describe the physical mechanisms leading to the sensitivity of certain Raman modes to the structure and interactions of nucleic acids. Starting from the description of known marker bands we will demonstrate how this method works to solve more practical problems related to interactions of nucleic acids with drugs and proteins.

Four important kinds of information can be extracted from RS studies:

(1) H-bonding between bases;
(2) noncovalent interactions between bases (base stacking);
(3) structural conformations;
(4) intermolecular interactions of proteins, drugs, and metal ions with nucleic acids.

In order to understand the complex vibrational spectra of nucleic acids, the lower molecular weight building blocks must be considered first. Nucleic acids are composed of nucleotides. The main components of nucleotides are a heterocyclic base, a sugar, and a phosphate group. Strong features from heterocycles and bands from symmetric vibrations of the phosphate group dominate in the Raman spectra of nucleic acids. Consequently, only those bands will be considered in this section. Characteristic vibrations of the main groups of nucleic acids as well as important marker bands are summarized in Table 7. Interpretation of the spectra is based on isotopic H/D, $^{14}N/^{15}N$, and $^{16}O/^{18}O$ substitution, comparison with model compounds, normal coordinate analysis, and application of the UV/RR approach.[60–62,86,87] H-bonding interactions can be followed by RS only if certain vibrational modes are concentrated on the motions of atomic groups involved in the bonding. The possible sites for H-bonding interactions are the NH and NH_2 donor groups and C=O and N acceptor groups in base residues as well as oxygen atoms of the phosphate group. Because protons of donor groups are easily exchangeable by deuterons, vibrations of these groups can be unambiguously distinguished by frequency shifts upon H_2O/D_2O solution exchange (Table 7). The strength of the UV/RR approach should be mentioned in this context. While bending vibrations of NH_2 groups (δNH_2) were not resolved using visible excitation,[86] these modes become prominent for A, cytosine (C), and G bases with UV-excited spectra[87] (Table 7). Vibrations of carbonyl groups ($\nu C{=}O$) occur in a rather narrow frequency range (1650–1700 cm^{-1}) and differentiation between $C_2{=}O$ and $C_4{=}O$ modes in thymine (T) and uracil (U) bases was performed by ^{18}O labeling and exploring the high sensitivity of the intensity of bands in the UV/RR excitation range (200–266 nm) on λ_{ex} (Table 7). Noncovalent interactions between bases (stacking) can be followed effectively by UV/RRS. In this case changes in intensity of the bands associated with the vibrations of purine and pyrimidine rings are monitored. Briefly, the mechanism can be described as follows: stacking of heterocyclic rings suppresses ε of the electronic absorption transition in the UV region. Because the RR enhancement is proportional to ε^2, the corresponding intensity of UV/RR bands markedly decreases. For example, the intensity of the breathing motion of the imidazole ring at 730 cm^{-1} in an A base residue decreases upon stacking (Table 7). The third important issue for molecular biologists, where the Raman technique can be valuable, is the structure of nucleic acids. The double helix structure is flexible and several conformational forms labeled as *A*, *B*, *C*, and *Z* were distinguished. Coupled X-ray diffraction (XRD) and Raman studies led to the elucidation of structural conformation marker bands[60,61,88] (Table 7). The conformational sensitivity of the imidazole ring breathing modes at 730 and 679 cm^{-1} observed for A and G base residues (Table 7) arises from the orientation effects around the N–R bond. From two observed symmetric phosphate stretching bands, the vibration of bonded oxygen atoms ($\nu_s PO_2'$) located at 740–850 cm^{-1} is the most sensitive marker band of structural conformations, due to the influence of rotation around the $R{-}O'$ bond on the frequency. The characteristic vibrations of different structural conformers useful for Raman examinations are summarized in Table 8.

Next, application of RS for the analysis of intermolecular interactions between nucleic acids and drugs, proteins or metal ions will be considered. The H-bonding marker bands and vibration of exposed oxygen atoms from the phosphate group ($\nu_s PO_2$) are usually affected by ligand binding. The power of vibrational spectroscopy (Fourier transform infrared (FTIR) and RDS) was recently demonstrated by analysis of drug (aspirin) interactions with DNA.[89] Upshifts in Raman frequencies indicated that at low drug concentrations, aspirin binds through the three main sites in DNA:

(1) the phosphate backbone PO_2 group ($\nu_s PO_2$ shifted from 1093 cm^{-1} in the free state to 1095 cm^{-1} upon binding);

(2) the A N_7 atom (bands at 1342 and 1304 cm^{-1} shifted to 1344 and 1306 cm^{-1});

(3) the T O_2 atom (band at 1661 cm^{-1} shifted to 1670 cm^{-1}).

The Raman investigations of binding between the model dinucleotide compound and protein led to the identification of specific binding sites.[90] In this work UV-excited (240–250 nm) RR spectra have shown the interaction of protein ribonuclease with dinucleotide through H-bonding involving the particular N_3 atom in the C base residue.[90] The marker band at 1526 cm^{-1} was found to be specifically upshifted in bonded dinucleotides (Table 7). Formation of complexes between nucleic acids and proteins was extensively investigated by Benevides et al.[88] Specific marker bands for bonded DNA were recognized. Interactions of drugs (at low concentrations) with DNA can be effectively examined through the SERS approach.[32]

The potential of the SERS technique in analysis of components of nucleic acids at the trace level was also demonstrated.[91,92] RNA[91] and DNA[92] bases were successfully detected in real time in a combined SERS–flow injection analysis (FIA) system. Figure 12 demonstrates the sensitivity of the SERS technique.[92] Characteristic bands from the adenosine base can be easily recognized after a 50-μL injection of solution containing as little as 800 pmol of biomolecules. addition to the sensitivity, the reproducibility is also impressive and encouraging.

6.4 Lipids and Biomembranes

Lipid bilayers are the general components of biological membranes and serve as a matrix for proteins. RS has proved to be valuable in providing information on phase transitions and order in lipid bilayers as well as on interactions of lipids with membrane perturbants such as proteins or drugs.[63–66] In this section two main problems will be considered:

(1) the relationship between lipid bilayer order parameters and Raman marker bands, and
(2) perturbations induced in the lipid structure by drugs and proteins.

Table 9 summarizes the phospholipid characteristic vibrations and marker bands useful in the structural analysis of lipid bilayers. The structure of a typical phospholipid, dipalmitoylphosphatidylcholine (DPPC), is also shown. Three order parameters, I_{2935}/I_{2880}, I_{2850}/I_{2880}, and I_{1088}/I_{1130} have been shown to be useful for monitoring the self-organization of lipids, the main elements of membrane structure. This is because the C–H stretching (2800–3000 cm^{-1}) and C–C skeletal (1000–1200 cm^{-1}) modes are sensitive to the intermolecular (between chains) and intramolecular (within chain) interactions to a different degree. While C–C skeletal stretches reflect only the changes in **T/G** conformation (intramolecular order), the C–H modes are sensitive to both **T/G** (intramolecular) and lateral chain–chain (intermolecular) interactions. Phase transitions between the bilayer gel and the liquid crystalline phase can be sensitively monitored using the dependence of the appropriate order parameter (Table 9) on the temperature.[63–65]

Interactions of polypeptides, proteins, nucleic acids or drugs with lipid bilayers induce changes in the bilayer structure affecting marker bands and providing the possibility of studies by RS.[65] Depending on the interaction type, ordering or disordering of lipid bilayers was observed. For example it was established that the charged polypeptide poly-L-lysine raises the transition temperature of zwitterionic phosphatidylcholines by 7 °C, suggesting that the interaction is stronger in the gel phase than in the liquid crystalline phase.[65] By contrast, an intrinsic membrane protein, the coat protein of filamentous phage viruses, lowers the phase transition of lecithin bilayers. In general, Raman data indicate that intrinsic membrane proteins, interacting over a large surface area with acyl chains, induce a higher number of **G** conformers within chains and lower the mobility of the chains. On the other hand, the extrinsic proteins interact mainly through the charged groups and in general increase the transition temperature.[65]

Table 9 Characteristic vibrations and marker bands of lipids[a]

Frequency (cm^{-1})	Assignment	Structural information	Order parameters
Structure of typical phospholipid molecule (DPPC)			
			
		Acyl chain region	
2956	$\nu_s(CH_3)$		(1) Parameter I_{2935}/I_{2880} monitors acyl chain disorder/order arising from latera chain–chain interactions and **G/T** isomerization (inter- and intramolecular interactions)
~2935 br	$\nu_s(CH_3)$ FR	Both intra- and intermolecular interactions	
~2847 br	$\nu_s(CH_2)$ FR with 2 $\delta(CH_2)$		
2880 vs	$\nu_{as}(CH_2)$	Both intra- and intermolecular interactions	(2) Parameter I_{2850}/I_{2880} directly monitors acyl chain disorder/order arising from lateral chain–chain interactions (intermolecular interactions)
2847 s	$\nu_s(CH_2)$	Both intra- and intermolecular interactions	
1457 vs	$\delta(CH_2)$	Intermolecular order; acyl chain packing; lattice subcell configurations	(3) Parameter I_{1088}/I_{1130} monitors extent of **G/T** isomerization (intramolecular interactions)
1441 vs	$\delta(CH_2)$		
1296 vs	$\iota(CH_2)$ twist

6.5 Dynamics in Biomolecules

Understanding the specific functions of biomolecules requires that the dynamics of conformational transitions and bonding with transient species are described in molecular detail. That is, techniques sensitive not only to the structure of biomolecules but also having nanosecond or even picosecond time resolution must be applied. Recent progress in laser technology and optical detection has enabled time-resolved Raman (TR^2) spectroscopy to become one of the most powerful methods in the study of ultrafast biomolecular events.[38,67–69] Due to the intrinsic weakness of the Raman process, the resonance-enhancement phenomenon is usually explored in such studies, and the technique is labeled as TR^3 spectroscopy. There are two essential steps in TR^3 experiments: initiation of the process, and monitoring of the process. Based on the process initiation protocols, the following methods can be distinguished:[67]

(1) rapid-mixing methods;

(2) light-initiated methods using continuous wave (CW) lasers:

- rapid-flow method
- spinning-cell method;

(3) light-initiated methods using pulsed lasers:

- single-pulse method
- dual-pulse method (''pump'' laser beam for initiation of the process and a different wavelength ''probe'' beam for process monitoring).

This TR^3 strategy was successfully applied to numerous biological systems, including heme enzymes, photosynthetic reaction centers, and visual pigments.[67] In the case of heme enzymes, the fast light-driven de-ligation of the CO adduct of the Fe(II) form serves as the initiation step. The following structural transformations of the protein matrix can be examined using either a probe beam at Soret absorption wavelengths to monitor the ν(Fe–N(His)) mode evolution, or a UV-probe beam to monitor changes in aromatic amino acid residues by exploring the UV/RR phenomena. The relationship between the structure of the protein matrix and the ligation state of the heme group in hemoglobin was demonstrated by Rodgers et al.[93] In this work the photolysis of hemoglobin-bound CO was initiated by the 419-nm laser pulse and the delayed 230-nm pulse served for the selective excitation of the transient UV/RR spectra from the Trp and Tyr residues in protein. Similar transient UV/RR spectra of the aromatic amino acid residue Tyr excited using a 240-nm probe beam were successfully applied for the monitoring of millisecond or even nanosecond structural changes in Bacteriordopsin initiated by the 515-nm pump beam.[94] As another interesting example to illustrate how the dynamics of biomolecules can be seen through RRS, the folding and unfolding reaction of cyt *c* will be considered briefly. Recently, a rapid solution-mixer with a 100-μs time resolution was coupled with RRS, providing the ability to monitor the folding/unfolding dynamics of cyt *c* with sub-millisecond resolution.[95] The initiation of folding was achieved by rapid dilution of denaturant-unfolded protein with an excess of buffer solution. The low-frequency mode (at 394 cm^{-1}) of the ferrous heme form associated with the vibration of the covalent thioether linkage between the heme and the polypeptide [$\delta(C_\beta–C_\alpha–S)$][81] served as the folding/unfolding marker band. Figure 13 demonstrates the development of the low-frequency spectrum during the folding reaction.[95] In the native folded state this band is intense, because of the twisting and tension of the heme group induced by the surrounding polypeptide. This band virtually disappears in the unfolded state, due to the more planar structure of the heme group. It is clear

Figure 13 Time evolution of the low-frequency RR spectra of cyt *c* following the initiation of folding. The ferrous CO-bound form of the protein was unfolded in 7.0 M guanidine hydrochloride (Gdn-HCl) and refolded in 0.7 M Gdn-HCl at neutral pH. The insert is the decay curve of the unfolded form obtained by monitoring the line at 394 cm^{-1}. The line at 491–498 cm^{-1} is assigned as the Fe–CO stretching mode. [Reproduced by permission of American Chemical Society from S.-R. Yeh, S. Han, D.L. Rousseau, *Acc. Chem. Res.*, **31**(11), 727–736 (1998).]

from Figure 13 that microscopic details of the folding reaction can be monitored in real time by RRS.

6.6 Raman Microscopic Analysis of Biological Systems

The structural sensitivity inherent to vibrational spectroscopy is combined with spatial resolution of 0.1–2 μm in MRS. Such a combination makes the MRS technique extremely attractive for applications in molecular biology such as analysis of cell components,[35,70] drug distribution,[96] or identification of the constituents of the cell membrane.[70] Recent introduction of UV/RRS in this field has considerably increased the selectivity and sensitivity of the MRS technique for molecules absorbing in the 180–300-nm region.[35] There is a growing interest in the application of the MRS approach to in vivo analysis of biomaterials.

Figure 14 In vivo RS measurements of human skin: (a) inverted microscope used for measurements; (b) in vivo Raman spectra of the stratum corneum at different anatomical regions measured at the skin surface. The spectra are from a single person: line A, fingerprint; line B, thenar; line C, dorsal surface of the middle finger; line D, volar aspects of the forearm. Spectrum A was measured in 180 s, all other spectra in 120 s. Objective 63 × 0.7. Excitation wavelength 850 nm, power 100 mW. [Reproduced by permission of John Wiley & Sons from P.J. Caspers, G.W. Lucassen, R. Wolthuis, H.A. Bruining, G.J. Puppels, *Biospectroscopy*, **4**, 31–39 (1998).]

Caspers et al.[97] have studied human skin in vitro and in vivo using a confocal Raman microspectrometer. The inverted microscope principle shown in Figure 14(a) was used for the in vivo Raman measurements. A CaF_2 window serves as support for the sample of interest. The required depth with the 9-μm resolution was achieved by translating the objective vertically. It was possible to record Raman spectra with 0-μm depth directly from the skin. Differences in several spectral regions (1640–1680 cm^{-1} amide I region; 1240–1300 cm^{-1} amide III region; bands at 1415 cm^{-1}, 855 and 880 cm^{-1}) can be easily identified from Figure 14(b) by comparing Raman spectra from different places on the skin. Variations in human moisturizing factors and lipid contents were suggested as possible reasons for some observed spectral variations. These results demonstrate the possibility of obtaining noninvasive vibrational spectra from living skin that contain information about the composition and structure of different places and layers of the skin.

7 FUTURE DEVELOPMENTS OF RAMAN SPECTROSCOPY

Advances in laser technology will make UV lasers cheaper. Because electronic systems of important biological structures such as bases of nucleic acids, aromatic amino acid residues, and peptide groups have electronic transitions in the 180–300 nm range, the applications of UV/RRS will rapidly expand.

There is some hope that progress in the preparation of more reproducible and stable surfaces for SERS will expand the application of this technique to monitoring traces of biomolecules in more applied investigations.

With a further reduction in the price of combined FTR/FTIR instruments, routine characterization of biosamples using vibrational spectra, especially at higher concentrations, will become common.

The progress in quantitative analysis by RS is connected to the development of simple sensitivity-calibration procedures and the evolution of detection systems.

The combination of highly sensitive Raman techniques (RR, UV/RR and SERS/SERRS) with the submicrometer spatial resolution ability of MRS is encouraging,

and holds promise for the wide expansion of vibrational spectroscopy to the analysis of single living cell components, leading to direct biomedical applications. However, problems with the laser-induced photodegradation of the sample will be apparent in this field.

8 COMPARISON WITH OTHER SPECTROSCOPIC METHODS

In this section the structural information and sensitivity of RS will be compared with IR, ultraviolet/visible (UV/VIS) absorption, and Fl techniques. An important feature of modern RS is the variety of techniques for exploring the Raman phenomenon (Table 1). Thus in making any comparison the technique will be specified. We will focus our attention on RS and IR techniques.

8.1 Structural Information

The main disadvantages of UV/VIS and Fl techniques are their lack of structural sensitivity. In contrast, two vibrational spectroscopic techniques, RS and IR, are able to provide rich structural information on the molecular systems. The resolution of vibrational spectroscopies is several orders of magnitude higher than for UV/VIS or Fl. For this reason we will concentrate on a comparison of the IR and RS methods. The first advantage of RS is the weak Raman scattering from water, in contrast to IR absorption. Therefore biomolecules can be studied in their natural environment. Secondly, resonance and surface-enhancement effects are possible for RS, providing the possibility of selectively monitoring the structure of certain molecular groups or adsorbed species. This is extremely important for large molecular systems such as biomolecules, due to interpretation problems. Third, ρ measurements provide an elegant way for assigning the vibrations according to their symmetry. Fourth, Raman spectra can be easily recorded over a wide frequency range ($100-4000\,cm^{-1}$), in contrast to IR spectra. Thus structurally important, low-frequency, metal–ligand vibrations can be studied using RS.

8.2 Sensitivity

The main disadvantage of RS compared with IR for analytical applications is the difficulty in establishing the analyte concentration from the Raman intensity, because the value of the Raman cross-section of an analyte molecule is usually unknown or is difficult to estimate. In addition, Raman intensities depend on many factors.[1] For this reason internal standard methods are usually employed in RS.[1] The sensitivity of IR spectroscopy, for example in studies of protein–ligand binding, is of the order of $\sim 10^{-3}$ M[52] (by monitoring the ligand internal mode); this is higher than nonresonance RS. In the case of RRS, however, the same protein–ligand systems can be monitored by low-frequency vibrations at concentrations in the order of $\sim 10^{-5}$ M.[52] The most sensitive technique, used for the determination of trace levels of fluorophores or even single molecules, is Fl spectroscopy. However, single molecules have also been detected recently using SERS and SERRS.[10,11] High sensitivity and also structural specificity were evident from these experiments.

Recently the sensitivity limits for the analysis of proteins with nonresonant RS and RDS were considered using a CCD detection system and an axial transmissive Raman spectrometer.[98] Good spectra were collected from 100-μM concentrations of protein. Finally, as can be seen from Figure 12, it is possible to detect adenosine at the 800-pmol level in a 50-μL sample using the SERS technique.

ACKNOWLEDGMENTS

The author would like to thank Dr Adolfas Gaigalas, Dr Vincent Vilker, and Dr Vytas Reipa from the Bioprocess and Engineering group at NIST (Gaithersburg, USA) for stimulating discussions and support during his stay at NIST and later. He also thanks Dr Rimas Jakubėnas for useful discussions and assistance in preparing figures.

ABBREVIATIONS AND ACRONYMS

A	Adenine
Az	Azurin
C	Cytosine

In order to detect and analyze single biomolecules, near-field microscopes and conventional far-field microscopes are used. Spectroscopic experiments are now possible to test predictions of quantum mechanics in a very direct way. With biological macromolecules, chemical reactions can be seen directly in the microscope. Mechanical properties of individual macromolecules can be measured with very high precision. This allows a very basic process of life, the generation of motion, to be understood in its finest details. Finally, single molecule experiments allow the DNA molecule to be studied in its full, practically unlimited individuality.

1 INTRODUCTION

The ultimate goal of sensitivity in analytical chemistry is single molecule detection, characterization and particularly the study of reactions of individual molecules with each other. The era of this grade of perfection of analytical chemistry has dawned with the end of the passing millenium and certainly the new millenium will become the time of single molecule physics, chemistry and biology. By the end of 1999, in addition to a number of reviews, special issues of regular journals[1–4] on single molecules and a book[5] are available in the literature.

2 HISTORY

One of the first single molecule experiments (1961) in analytical biochemistry is the study of the reaction of a single β-galactosidase molecule held in a microdroplet.[6] Widespread applications became possible in the 1980s, with the advent of near-field microscopies which allowed imaging, for example, of the orbitals of benzene molecules.[7] It came as a surprise that these micrographs (probably nanograph would be the better expression) revealed a threefold symmetry rather than a sixfold symmetry as one might have expected from the Kekulé formula. Later, individual atoms and molecules could be manipulated with the tips of such scanning microscopes (for these microscopy techniques see below). These pure detection techniques did not yet allow spectroscopy, since they were monochromic. Color and thus spectroscopy in the sense that it is typically used by the analytical chemist were not yet widely used. This problem was alleviated by the advent of the near-field scanning optical microscope. Then it became possible to use the

wavelength of an individual molecule which had already been exploited in bulk analytical or physical chemistry to obtain spectral information. The biggest surprise was the finding that normal – though high quality – fluorescence microscopes could be used for single molecule analysis. This was thought to contradict the Abbe criterion which states that the resolution of a classical far-field microscope is not better than 50% of the wavelength of the light used for illumination (0.5 μm for green light). The mistake of the sceptics was that they confused resolution with reproducibility of localization. When the molecules were prepared with sufficiently small concentration onto a surface, they had an average distance of several micrometers from each other: they no longer had to be spatially resolved, they just had to be visualized. Visualization of individual molecules is possible down to sizes of a few nanometers (see for example page 274 of Greulich[8]). The price one has to pay is that the molecules appear too large, but for many applications this drawback is acceptable. The classical fluorescence microscope has two significant advantages compared to the above-mentioned near-field microscopies. It is fast (standard temporal resolution is video frequency, 40 ms, and even this can be speeded up), i.e. the dynamics of molecules and reactions becomes experimentally accessible and preparation techniques can be easily adapted from bulk analytical methods. Thus, with the advent of classical fluorescence microscopy the path was paved to studying real single molecule reactions. Some studies dealt with small reactions such as the catalytic oxidation of CO on platinum 111.[9] Here it turned out that the individual molecule reaction just reflected what was known from bulk. A different situation was expected for biomolecules: since theoretical knowledge of protein structures had predicted that all individual enzymes of a species would differ slightly but distinctly from each other, it was no surprise that they revealed different reaction rates.[10] A particularly attractive target for single molecule studies is the DNA molecule. DNA is so variable that it is not possible to synthesize one copy of each possible DNA molecule only 120 basepairs in length (a typical gene would be much longer). The mass of the universe would not suffice (see for example page 161 of Greulich[8]). Due to this virtually unlimited variability, analysis of DNA single molecules, unlike conventional genome-megaprojects, may finally provide full information on DNA as a molecular individuum.

3 PREPARATION AND HANDLING OF SINGLE MOLECULES

Two types of single molecule solutions are interesting for single molecule research: highly diluted solutions of small molecules (single chromophores) and, on the other hand, biological macromolecules stained with a large number of chromophores.

3.1 Microfluidics for Single Molecule Handling

Typical bulk dye solutions are millimolar to micromolar. A solution with one molecule in the typical volume of 1 fL which is used in single molecule research corresponds to 10^{15} mol L^{-1} or approximately a nanomolar solution. These small concentrations can be obtained by conventional serial dilution. In order to prevent loss of single molecules to vessel walls, suitable materials are helpful, for example hydrophobic ones for hydrophilic molecules and vice versa. A problem is to set the time point for a reaction start. One approach is to premix the reaction partners, dilute them subsequently, transfer them to a surface and then observe the reaction. With such a strategy, the first minutes of the reaction are lost and therefore only slow reactions can be observed. An alternative approach is to bring the reaction partners onto a surface in separate nanodroplets and to start the reaction by fusing the latter at a preselected time. Here, the reaction can be observed a few seconds after mixing.

3.2 Preparation of Single Biological Macromolecules

A completely different approach is possible when biological macromolecules such as DNA, microtubules or actin filaments are involved. Such molecules can be coupled to micrometer sized polystyrene or silica spheres which act as a sort of handle. They can be handled micromechanically, or, more gently and precisely, by optical tweezers.[8] One successful strategy to start a reaction of such a macromolecule with a reaction partner is to use caged compounds: for example, many enzymes acting on DNA require magnesium. When the latter is present as a caged compound (and thus is inaccessible for the enzyme) the reaction cannot proceed. When the caged compound is disrupted by irradiating it with ultraviolet light, the magnesium is released and the reaction starts immediately.

3.3 Laser Micromanipulation for Handling of Individual Macromolecules

An interesting tool for handling of individual macromolecules are optical tweezers: a continuous infrared laser of moderate power, which is focused in a microscope to the theoretical (diffraction) limit. Light pressure and gradient forces push microscopic objects in the focus of the laser. By moving the focus, these objects can be moved along complex trajectories. Since only forces exerted by light are acting, no sticking of individual molecules to microtools or disruption by the latter occurs.

4 INTERACTION OF LIGHT WITH SINGLE MOLECULES

A single, light absorbing molecule is a unique quantum system which interacts with the light field. Such an interaction not only allows us to obtain unique information on the molecule, but also on the intrinsic properties of light. For example, a number of important experiments on which quantum mechanics are based only exist so far as ''Gedankenexperiment'' or have, at most, been experimentally verified only in a disputable way. Surprisingly for many, the famous quantum mechanical version of the double slit experiment is among these unsolved problems. This crucial experiment, where it is assumed that individual photons hit the double slit and interfere with each other or with themselves, has never been performed since it is difficult to produce single photons. In most cases wavetrains are produced by attenuating a laser, and this is not what the Gedankenexperiment needs. With single molecules one has for the first time the perspective to produce and use individual photons safely.

5 FLUORESCENCE CORRELATION SPECTROSCOPY AS A QUASI SINGLE MOLECULE TECHNIQUE

There are basically two strategies for the observation of single molecules: one may embed them in some sort of matrix and observe them at the surface of a substrate material, or one may study them directly in solution. The latter technique requires extreme dilution of the molecules and simultaneously extreme miniaturization of the observation volume. This has been achieved by investigating solutions of fluorescing molecules with a diffraction limited fluorescence microscope, i.e. in an observation volume of less than 1 fL. Basically, in such experiments the velocity of a molecule migrating through the tiny observation volume is measured. One detects a single molecule in a given volume, and after a preset time of waiting one looks to see if it is still there. Slow particles will be found several times, fast particles will be found only twice or three times. Mathematically, this is described by the correlation function (Equation 1)

$$G(t) = \sum I(t)^* \, I(t + T) \qquad (1)$$

where T is the waiting time.

$G(t)$ is related to the speed of the molecule which can be used to calculate the diffusion constant of the molecule. The latter can be used to estimate the molecular weight. Such experiments are often used to measure the binding of two individual molecules. This is possible when the two binding partners differ by at least a factor of 8–10 in size, for example the binding of an antigen to an antibody or the hybridization of a small DNA or RNA oligonucleotide to a long DNA or RNA molecule.[11] In such experiments, the smaller binding partner is made fluorescent. One will see the small partner as a fast diffusing object and the complex of small with large partner as a slow object. The correlation analysis not only allows the absolute migrating velocities to be measured, but also the ratio of free to bound molecules, i.e. the binding constants according to the mass action law. Since one needs to measure a number of molecules and molecular complexes to obtain such binding constants, fluorescence correlation spectroscopy is not a true single molecule technique, but it is a technique for very small concentrations. True single molecule techniques can be based on microscopies as described in the following.

6 MICROSCOPY OF SINGLE MOLECULES

6.1 Near-field Microscopies

The near-field microscopes all work according to a common basic principle: a sort of ultrafine stylus scans an object matrixwise and subsequently assembles an image from the data it has obtained. This data assembly takes some time and therefore the temporal resolution of these microscopes is limited to seconds or somewhat below seconds. In turn, the spatial resolution is better than with any other tool available to the analytical chemist or biochemist. The reason for this is that the stylus comes very close to the object under observation. It is the same principle as the stethoscope of a medical doctor: there, acoustic waves of a beating heart with wavelengths of meters can be exploited to localize the heart with an accuracy of centimeters. Therefore, the optical version of the near-field microscopes, the SNOM (scanning near-field optical microscope), has also been called the optical stethoscope. It has a typical spatial resolution of 60 to 80 nm and can be used as a highly localized spectroscope. The second near-field microscope used in the analysis of single biomolecules is the atomic force microscope (AFM). Here, a mixture of van der Waals, electrostatic and other forces is used to detect the molecule. Since these are all short range forces, one has to get closer to the molecule under observation and the spatial resolution is better than with the SNOM for ideal (hard) objects in the subnanometer range. The near-field microscope with the best resolution is the scanning tunneling microscope which, under favorable conditions, can detect submolecular structures as mentioned already in the historical overview. It needs electrically conducting objects.

6.2 Very Highly Sensitive Fluorescence: Dyes and Detectors

The near-field techniques for the detection of single molecules often require specific preparation protocols. Also, the tip of the detecting stylus is very sensitive and can easily break. The typical practical lifetime of such tips are hours or days at most. Therefore, near-field microscopies may easily become time-consuming and expensive. This may be one reason why classical far-field microscopy has got its chance in single molecule analysis. Here, light is the carrier of information and comparably gentle interactions can be used to study individual molecules. A disadvantage is that only molecules with a significant fluorescence yield or nonfluorescing molecules after labeling with a fluorescence dye can be investigated. Among biomolecules, NADH, flavines and other natural compounds occurring in biological cells are used. For biological macromolecules, a large number of fluorescing dyes is available which are known not, or only moderately, to modify the macromolecule's function. Many of these dyes have been developed to match with their absorption maximum the working wavelength of standard lasers.

Detecting single molecules by a fluorescence microscope is not so much a problem of the number of emitted photons. Since a molecule can, in principle, emit a light quantum every 10 ns, up to 100 million quanta might be expected from a single molecule per second. Two problems hamper this process: first, a dye molecule will decay after a few hundred up to a million cycles of excitation and emission into nonfluorescing derivative. Second, in order to excite a dye molecule at typical concentrations (see above), some 10^8 photons will pass the detection volume. In other words, one has a large number of unwanted photons per useful photon for the detection of the molecule. Optical filtering techniques are not completely sufficient to identify the useful photon. This is the major challenge for classical light microscopy in single molecule analytics.

Part of these problems may be overcome by replacing classical fluorescence dyes by nanocrystals or quantum dots. These are nanometer sized clusters of, for example, zinc sulfide capped cadmium selenide.[12] Their absorption and emission behavior is solely determined by their size: small clusters are blue, larger ones are red. An advantage of these quantum dots is their very good absorption and emission behavior; a disadvantage is their bulkiness.

6.3 Classical Far-field Microscopy for High Temporal Resolution

In spite of these problems, classical far-field microscopy is attractive since it provides high temporal resolution. When a fluorescence microscope is equipped with a standard TV CCD camera, one can obtain 25 images per second. This corresponds to a temporal resolution of 40 ms. Special cameras are much faster and millisecond resolution is easily available when one is willing to go a step beyond standard CCD recording. For low level light, as in single molecule research, cooled CCD cameras integrating over several image frames can be used, but then the temporal resolution is decreased correspondingly. When extreme sensitivities at high temporal resolution are required, single photon counting cameras are available. These are in principle arrays of microphotomultipliers, often with 250×250 pixel elements. In almost all cases the reduced (as compared to standard CCD cameras with 700×500 pixels) image size is completely sufficient, since single molecule observation requires only parts of a full visual field in a light microscope. For an overview on such cameras see Pilarczyk.[13]

Color information can be added by using a true color camera but they do not usually have the sensitivity described above. More efficient is the use of optical filters. Fast switching filter wheels and computer programs for exactly overlaying the different colors are available on the market.

7 SINGLE (NONBIOLOGICAL) MOLECULE SPECTROSCOPY

Since the energy states in molecules are not indefinitely sharp, absorption and emission lines have a nonzero width. From quantum mechanics, one can relate these widths with lifetimes of a specific energy state and with other properties of a molecule. The shape of such a line can be described by a Lorentzian curve. Line widths in bulk experiments detect an average over many slightly differing molecules – they are ''inhomogeneously broadened'' – i.e. they are much wider than the informative Lorentzians. Therefore, the advent of single molecule techniques represents a milestone for molecular spectroscopy. Even time resolved fluorescence studies on single molecules[14–16] and three-dimensional imaging are now possible,[17] not only in solid state, but also in solution.[18]

7.1 Reaching the Limits of Spectroscopy

One of the first steps towards single molecule spectroscopy was achieved with pentacene or terrylene molecules embedded into a *p*-terphenyl single crystal matrix (see for example chapter 1 in Basche et al.[5]). Many of these experiments were performed in the cold. Such experiments showed that very narrow line widths (10 MHz at 1 K) broadened by a factor of 100 when the temperature was increased by only 10° (chapter 2 in Basche et al.[5]).

7.2 A Direct View on Quantum Mechanical Properties

One of the probably most convincing single chromophore experiments deals with a central phenomenon of spectroscopy and quantum mechanics. A fluorescing dye molecule absorbs light and, after typically a few nanoseconds, re-emits it at a longer wavelength. Occasionally, by intersystem crossing, it goes into a triplet state. Quantum mechanics predicts that this state lives theoretically forever, in practice microseconds to hours (the latter is known from the phosphorescence of the face of a watch). In bulk experiments this prediction could be verified, but never directly seen. Several groups have now shown this process on the single molecule level: terrylene molecules were embedded in their *p*-terphenyl matrix and observed over a long period. During most of the time, they absorbed, re-emitted, re-absorbed and so on. Occasionally, they were ''off'' for a longer period. In some cases, this molecular blinking was attributed to transient oxidation. In other experiments oxidation could be excluded and the blinking was attributed to the quantum mechanic transition into the long lived exited triplet state. As long as the molecule is in this state, no further absorption and re-emission can occur: the molecule remains dark. This is the first direct visualization of a single-triplet transition: for the first time the observer has a direct view on a true quantum system (see chapter 1, page 52 in Basche et al.[5]).

7.3 Magnetic Resonance of Single Molecules

While near-field microscopy and optical far-field techniques represent the major tools for single molecule research, a few additional methods exist. One of the most important of these is the magnetic resonance technique. Usually, nuclear magnetic resonance (NMR) works with radiowaves and electron spin resonance with microwaves. In both cases, the energy per photon is small; one needs many of them to detect a spin and therefore the methods are not sensitive enough for single molecule detection. However, one can also detect the spin resonances optically (optically detected magnetic resonance, ODMR), and then single spin sensitivity can be achieved. This and other improvements of magnetic resonance techniques now allow single spins to be detected and analyzed.[19]

8 SINGLE MOLECULE BIOPHYSICS AND BIOCHEMISTRY

Single molecule techniques are even more important in studies of biological macromolecules. For some biological macromolecules the individual differences are not only interesting for reasons of basic research. Such differences may be important also for health and disease. For example, the malfunction of an enzyme may cause irregularities. Such a malfunction may develop by a sort of evolution and may only gradually turn into a true disease form. Early detection of such changes on the single molecule basis will probably allow early diagnosis and thus may help to prevent the outbreak of a disease.

8.1 Direct Observation of Single Molecule Reactions

The conformational dynamics and cleaving mechanisms of enzymes can be directly observed at surfaces.[20] The action of individual enzyme molecules in solution becomes accessible, for example, when a nonfluorescent substrate is converted into a fluorescent product or vice versa, or when the reaction with nonfluorescent partners can be made visible by a subsequent fluorescence reaction as is general practice in medical diagnosis or in nutrition chemistry. For example, the conversion of nonfluorescing NAD^+ into fluorescing NADH by individual molecules of lactate dehydrogenase has been observed by this approach. In the two droplet approach as described above, the reaction of some ten molecules has been observed. By the premix technique, quantized reaction rates have been found. The rates were multiple integers of a basic reaction rate. This was interpreted as the reaction catalyzed by one, two ... up to six enzyme molecules.[21] For this type of study the term ''single molecule enzymology'' has been coined.[22]

8.2 Nanometers and Piconewtons: Mechanical Properties of Single Macromolecules

The mechanical properties of filamentous molecules can be measured directly with optical tweezers. For this purpose again microbeads are biochemically coupled to the ends of the molecules and then pulled apart either by the stylus of an AFM or by optical tweezers. The force required to elongate such a molecule is measured.

8.3 The Tiniest Motors: Kinesin, Dynein and Myosin

Self driven motion and reproduction are two characteristic features of life. Both depend on molecular transport processes. In many of these processes, either dynein or kinesin molecules travel along rail-like filamentous structures called microtubules. Correspondingly, myosin molecules move along actin filaments. The action of a muscle, for example, results from the concerted operation of thousands of such tiny motors, which in most cases convert the chemical energy of an adenosine triphosphate molecule into motion. Typical single molecule experiments bind the rails (microtubules or actin) to a glass surface of a microscope slide and observe the single, fluorescently labeled motor protein gliding along the rails.

Alternatively, the motors are bound and the filamentous rails are held with double optical tweezers in suspension. When the molecular motor transports the rail, force is exerted on the optical tweezers, which can be measured with piconewton accuracy. Such experiments have shown that the force exerted by single motor proteins is of the order of a few piconewtons and the step width with which it moves along a rail is 8 nm for kinesin and probably also for dynein, while it may range from a few nanometers up to more than 10 nm for native and genetically modified myosin molecules with a different neck region. For kinesin, single molecule experiments under permanent load showed that models derived from bulk data, where permanent load of in vivo processes could not be simulated, cannot be correct. In these experiments, Michaelis–Menten kinetics, a very basic mechanism of biochemistry, could be measured on the single molecule level.[23] For myosin, per nanometer of a structural part called the neck region, the step width is 0.5 nm.[24] Similar experiments have been performed with RNA polymerase from *E. coli*. A surprise was that this enzyme exerts a force more than double that of the motor proteins, in spite of the fact that its task is not to generate motion but to read genetic information from DNA into RNA. A possible explanation for this finding is that this enzyme does not read from naked DNA but from DNA complexed with proteins (histones, nucleosomes) and that the force is required to read its way through these obstacles. The RNA polymerase experiments, similar to the kinesin experiments described above, also showed the importance of true single molecule experiments for the elucidation of the basic mechanisms of generation of motion.[25] Perhaps it is only an experimental curiosity: knots have even been tied into actin molecules.[26]

8.4 Receptor–Ligand Binding on a Single Molecule Basis

The imaging of single molecule diffusion[27] and the counting of single protein molecules at surfaces represent important steps for limiting the sensitivity analysis of disease processes. This may be binding to hormone receptors or antigen–antibody binding. A technique to count such binding processes has been developed by Löscher.[28] Even more detailed are studies on the forces between individual antibodies and their antigens.[29] The perspective of such studies is not only to learn details on the underlying binding process, but also to develop a force sensing microscope.

8.5 DNA as a Molecular Individuum

The unlimited variability of DNA molecules and the resulting need of single molecule studies has already been addressed above. Mechanical properties of individual DNA molecules can be studied for example by stretching them first in a shear flow and then observing by a fast video microscope camera how these filamentous structures collapse into random coils.[30] When DNA is overstretched, mechanical properties become sequence dependent.[31] A special double stranded DNA construct, which is overwound and thus supercoiled, can be stretched and thereby denatures locally, i.e. the double strand becomes opened into two single stranded stretches of DNA.[32] A similar experiment separated two complementary strands of DNA mechanically, whereby obviously the double helix was unwound without prior overwinding. The required separation force is different for GC- and AT-rich sequence elements and thus information on the base composition of a single DNA molecule can be obtained with an accuracy of 100–500 bases.[33] Since DNA exists in different structural forms, for example B-DNA and Z-DNA with different lengths per basepair, structural transitions can be exploited to construct a nanomechanical device.[34] Studies on the behavior of single DNA molecules in gels have a quite different motivation.[35] Here, the mechanism of gel electrophoresis of large DNA fragments is studied.

Of particular interest is the direct observation by light microscopy of DNA cutting, since this is a process occurring in many processes in life sciences. The observation of such reactions in electrophoresis gels has been termed optical mapping.[36] Phosphodiester bond breaks have been directly observed in a dual beam optical microscope[37] and the binding of RecA molecules to a single DNA molecule held by double beam optical tweezers was visualized directly in a light microscope.[38] The enzymatic cleavage of an individual Lambda phage DNA molecule by the restriction endonuclease Apa1 has been observed.[39,40] One of the most beautiful single molecule experiments is perhaps the visualization of an RNA polymerase molecule running along a DNA molecule. The processivity of this enzyme can thus be directly seen, without any model assumptions.[41]

This article describes recent progress in the field of vibrational optical activity (VOA) as a probe of the structural properties of pharmaceutical and biological molecules. A strong emphasis is placed on vibrational circular dichroism (VCD) owing to its more advanced state of development. Raman optical activity (ROA) is included in the first two sections for completeness; other reviews give additional information about ROA.[1–3,8] The article focuses on the practical aspects of VCD spectral measurement and interpretation. This is supplemented by examples that serve to illustrate the principal areas of VOA application. VCD is defined as the difference in the absorbance of the left circularly polarized (LCP) versus right circularly polarized (RCP) infrared (IR) radiation for a chiral molecule undergoing a vibrational transition. A pair of enantiomers will produce VCD spectra that are equal and opposite in sign and a racemic mixture will have a null VCD signal. VCD can be measured for all kinds of chiral molecules, irrespective of their size. In practice, measurements are often carried out in solution but, with the new advances in instrumentation, it is now possible to measure spectra of solids and mulls. Compared to other optical techniques such as electronic circular dichroism (CD) and IR absorption, VCD is unique because it combines the optical activity property of CD with the rich structural fingerprint region of IR. The discovery and first measurements of VCD occurred in the early 1970s. Although over a dozen practitioners have published close to a 1000 papers since then, it is only recently that VCD instrumentation has become available commercially for nonspecialists. Applications span a variety of fields from chemical and pharmaceutical to biological. The VCD technique can be used for the determination of absolute configuration of small chiral molecules or larger natural products. It can also be used to follow a chiral synthesis both for stereochemistry and for optical purity, and to study the secondary structure of large proteins and small peptides, and the conformation of nucleic acids and sugars. Some recent reports have also shown the unique sensitivity of ROA in the study of viruses and in protein-folding experiments. VOA is now fulfilling its promise of becoming a technique that is broadly used for stereochemical and conformational studies of all varieties of chiral molecules, both natural and synthetic.

1 INTRODUCTION

VOA is defined as the differential response of a molecule to LCP versus RCP radiation during a vibrational transition.[1,2,3] There are two principal forms of VOA, an IR form referred to as VCD, and a Raman form known as ROA. VCD is the extension of CD measured for electronic transitions from the visible and ultraviolet regions into the IR region where vibrational transitions

Encyclopedia of Analytical Chemistry

occur. For Raman scattering, there is no classical analog, thus ROA is measured as circularly polarized (CP) intensity differences in the incident laser radiation, the scattered radiation, or both. As with CD, VOA is zero unless the sample possesses molecular chirality, either through its constituent chiral molecules or through a chiral spatial arrangement of nonchiral molecules.

1.1 Definitions of Vibrational Circular Dichroism and Raman Optical Activity

There is only one form of VCD as it involves the differential response of a molecule undergoing a one-photon transition. The spectra are typically measured as the difference in the absorbances of a molecule for LCP minus RCP light (Equation 1):[4]

$$\Delta A(\bar{\nu}) = A_{\mathrm{L}}(\bar{\nu}) - A_{\mathrm{R}}(\bar{\nu}) \tag{1}$$

where $\bar{\nu}$ is the wavenumber frequency in units of cm^{-1}. Alternatively, the effects of path length l and concentration C may be eliminated by using the absorption coefficient (Equation 2):

$$\Delta\varepsilon(\bar{\nu}) = \frac{\Delta A(\bar{\nu})}{lC} = \varepsilon_{\mathrm{L}}(\bar{\nu}) - \varepsilon_{\mathrm{R}}(\bar{\nu}) \tag{2}$$

The ROA method is more complex than VCD both experimentally and theoretically. There are four distinct forms of ROA involving CP radiation and an additional four involving linearly polarized light, although the latter are more specialized and will not be discussed further. If we designate the polarization state of the incident laser beam with a superscript and that of the scattered radiation with a subscript, the four forms of CP/ROA can be written as in Equations (3–6):[5]

$$\Delta I_{\alpha}(\bar{\nu}) = I_{\alpha}^{\mathrm{R}}(\bar{\nu}) - I_{\alpha}^{\mathrm{L}}(\bar{\nu}) \tag{3}$$

$$\Delta I^{\alpha}(\bar{\nu}) = I_{\mathrm{R}}^{\alpha}(\bar{\nu}) - I_{\mathrm{L}}^{\alpha}(\bar{\nu}) \tag{4}$$

$$\Delta I_{I}(\bar{\nu}) = I_{\mathrm{R}}^{\mathrm{R}}(\bar{\nu}) - I_{\mathrm{L}}^{\mathrm{L}}(\bar{\nu}) \tag{5}$$

$$\Delta I_{II}(\bar{\nu}) = I_{\mathrm{L}}^{\mathrm{R}}(\bar{\nu}) - I_{\mathrm{R}}^{\mathrm{L}}(\bar{\nu}) \tag{6}$$

Here, the intensities are a function of the wavenumber shift of the scattered radiation. The form of ROA given in Equation (3) is the one first discovered and measured since the 1970s. It is called incident circularly polarized (ICP) ROA because only the polarization state of the incident beam is switched between RCP and LCP states. The polarization state of the scattered light α is a fixed linearly polarized or unpolarized state. Note that the definition of ICP/ROA is opposite that of VCD with respect to RCP and LCP radiation. This is the result of historical convention, and not the result of any deep underlying principle. In fact, recent work on the theory of resonance Raman optical activity (RROA) has revealed a direct connection between the electronic CD of the resonant state and the observed RROA in which the magnitudes are the same and the sign correlation is opposite owing to the opposite definitions of CD and ROA.[6] The other three forms of ROA involve changing the polarization state of the scattered radiation between RCP and LCP states. Equation (4) describes scattered circularly polarized (SCP) ROA in direct analogy to ICP/ROA. The other two forms of the ROA in Equations (5) and (6) describe the in-phase and out-of-phase forms of dual circularly polarized (DCP) ROA, designated with subscripts I and II, respectively (i.e. DCP_I and DCP_{II}).

Another variable of ROA is the scattering angle. All early measurements of ROA were carried out for right-angle scattering. In the 1980s, the advantages of backscattering ROA were realized[7] and, currently, nearly all measurements of ROA are carried out with backscattering geometry, either as unpolarized ICP/ROA, DCP_I/ROA, or unpolarized SCP/ROA.[8]

1.2 Comparison of Vibrational Circular Dichroism and Raman Optical Activity

Both VCD and ROA were discovered in the early 1970s.[1] Each has evolved both experimentally and theoretically to a sophisticated state. Each is very sensitive to the stereostructural features of chiral molecules in solution, and they have similar differences and advantages to their parent spectroscopies IR absorption and Raman scattering. In fact, neither VCD nor ROA can be successfully measured unless an excellent parent IR or Raman spectrum can first be measured. Owing to the more complex nature of carrying out measurements and theoretical analyses, ROA has lagged behind VCD in applications to structural analysis. Further, both the instrumentation for the routine measurement of VCD and software for the ab initio calculation of VCD are now commercially available. Thus, VCD is much more accessible for use by nonspecialists for practical applications, in both academic and industrial settings.

Despite these differences in instrumental and theoretical commercial availability, VCD and ROA are unique complementary forms of VOA, each having its own advantages or disadvantages in particular kinds of applications. The situation is analogous to the complementary nature of IR and Raman spectroscopy in general where differences in sensitivity, solvent interference, and sampling have a role in the selection of the preferred approach. It has been shown that VCD and ROA spectra are strongly noncorrelated in the signs and relative intensities of the bands. The only common element is the structure and vibrational motion of the molecules under study. Thus, adding an ROA spectrum to a study where the VCD spectrum has already been obtained yields new

useful information. Both ROA and VCD have been used for conformational elucidation, optical purity measurements, and the determination of absolute configuration. In both VCD and ROA the abundance of vibrational transitions, each with its own probe of the stereochemistry of the chiral molecule, provides a wealth of structural information.

2 HISTORY AND INSTRUMENTATION

2.1 Vibrational Circular Dichroism Instrumentation

The first measurements of VCD were achieved in the early 1970s with instruments that were relatively crude by today's standards, but they demonstrated the existence of VCD as a natural phenomenon that could be used to learn about the detailed structure and dynamics of chiral molecules.[9,10,11] Later improvements in VCD spectrometers extended the wavelength coverage from the region of hydrogen stretching modes into the mid-IR region where a greater variety of vibrational transitions could be observed.[12] A particularly important advance was the advent of Fourier transform infrared (FTIR) methods for VCD measurement.[13] Virtually all modern VCD spectrometers, including all commercially available models, are now FTIR/VCD spectrometers.

During the 1990s, accessory modules for the measurement of FT/VCD (Fourier transform/vibrational circular dichroism) have been offered by several manufacturers of FTIR spectrometers. In the case of Bomem, Inc., a completely dedicated stand-alone, factory-aligned FT/VCD spectrometer has become commercially available, the Chiralir™, which has opened the way for widespread applications of VCD spectroscopy not only in academia but also in industry.[14]

The principal applications of VCD spectroscopy include measurements of the conformation, absolute configuration, and enantiomeric excess of chiral molecules.[4] Most of the molecules of interest for study with VCD are biological in origin. Many are molecules of pharmaceutical interest. The most unique application of VCD is its ability to determine absolute configuration in conjunction with ab initio calculations. Remarkably close matches have been achieved between experimental VCD spectra and the corresponding spectra calculated from first principles using quantum mechanical calculations.

2.2 Raman Optical Activity Instrumentation

Early ROA instrumentation was based on scanning dispersive spectrometers.[15,16] Light levels were low as nonholographic grating technology was used and two or three grating stages were necessary for the reduction of stray Rayleigh radiation. As a consequence, spectra spanning $1000\,cm^{-1}$ or longer required a day or more to measure. The experimental set-up used in these early measurements was always right-angle depolarized ICP measurements.

Several advances over the years changed this situation dramatically. These included the advent of backscattering geometry, back-thinned charge-coupled detectors, and holographic transmission gratings. Currently, ROA spectra spanning $2000\,cm^{-1}$ for the most favorable samples can be discerned in less than 10 s.[17,18] High-quality spectra for these samples can be obtained in approximately 1 min. This advance in speed and sensitivity has opened the way for more sophisticated applications of ROA, such as studying the folding properties of proteins as a function of temperature and other perturbations.

Most recently, attempts are underway to reduce ROA instrumentation to routine operation. These efforts include the introduction of fiber optic coupling to eliminate the effects of beam wander and loss of the precise alignment needed for artifact-free measurements.[8] When this is achieved, ROA is likely to join VCD as a technique available to chemists and biologists wishing to study the conformation of molecules of chemical, biological, and medical interest.

3 INSTRUMENT OPERATION AND PERFORMANCE

3.1 Fourier Transform Vibrational Circular Dichroism Instrumentation and Measurement

3.1.1 Basic Principles

The measurement of a VCD spectrum begins with the measurement of the IR spectrum of a sample. If the IR spectrum cannot be measured with good spectral quality, there is little chance of measuring the corresponding VCD spectrum. The general recommendation is to obtain the IR spectrum with a decadic absorbance in the range 0.1 to 1.0. The expression for the absorbance, $A(\bar{\nu})$, is given by Equation (7):

$$A(\bar{\nu}) = -\log_{10} \frac{I(\bar{\nu})}{I_0(\bar{\nu})} \tag{7}$$

An absorbance of 1.0 corresponds to a percentage transmission value (100 times the ratio in square parentheses) of 10%, whereas an absorbance of 0.1 corresponds to a percentage transmission of about 80%. If the absorbance is greater than 1.0, too little light reaches the detector, whereas if the absorbance is less than 0.1 the sample absorbs too little of the incident IR beam. The optimum value of the absorbance for VCD measurements is approximately 0.4.

In order to measure a good VCD spectrum, it is essential to consider additional issues beyond the quality of the parent IR spectrum. These include the quality of the VCD baseline, the selection of the spectral region, and the setting of the polarization modulator. In addition, for FT/VCD measurements, the appropriate phase correction must be used to obtain the desired spectrum.

3.1.2 Instrument Block Diagram

A simple block diagram for the measurement of FT/VCD in the mid-IR region is given in Figure 1. The design corresponds to the so-called double modulation approach to FT/VCD measurement. Here two interferograms are present simultaneously at the detector, one for the ordinary IR spectrum and the other for the VCD spectrum. The method involves measuring each of the interferograms and ratioing the raw VCD spectrum to the raw transmission spectrum of the sample. IR radiation from an interferometer first passes through an optical filter to isolate the spectral region of interest. The beam continues through a linear polarizer that defines a single state of polarization and then on to a ZnSe photoelastic modulator (PEM) that modulates the polarization between LCP and RCP states at a frequency of 37 kHz. The chiral sample is placed directly after the PEM and the beam is focused with a lens to a HgCdTe detector that is cooled with liquid nitrogen. The detector signal is preamplified and divided into two paths. One is the ordinary IR path that represents the FTIR interferogram of the sample. The expression for the IR transmission interferogram is given by Equation (8),

$$I_{DC}(\delta) = \int_0^\infty I_{DC}(\bar{\nu}) \cos[2\pi\bar{\nu}\delta - \theta_{DC}(\bar{\nu})]\, d\bar{\nu} \qquad (8)$$

where the subscript DC refers to the constant nature of this interferogram relative to the high-frequency polarization modulation. Here δ is the path difference in the interferometer and $\theta_{DC}(\bar{\nu})$ is the Fourier phase function. After digitization, phase correction, and Fourier transformation, one obtains the IR (DC) transmission

Figure 1 Optical–electronic diagram for a typical FT/VCD spectrometer.

spectrum of the sample given in terms of the average transmissions for LCP and RCP radiation as (Equation 9)

$$I_{DC}(\bar{\nu}) = \tfrac{1}{2}[I_R(\bar{\nu}) + I_L(\bar{\nu})] \qquad (9)$$

The other path is to the lock-in amplifier, as shown in Figure 1, referenced to the PEM modulation frequency. The output of the lock-in is the interferogram associated with the VCD which is given by Equation (10)[19]

$$I_{AC}(\delta) = \int_0^\infty I_{AC}(\bar{\nu}) \exp(-2V\bar{\nu}\tau) \cos[2\pi\bar{\nu}\delta - \theta_{AC}(\bar{\nu})]\, d\bar{\nu} \qquad (10)$$

where the exponential factor describes the effect of the lock-in time constant τ of the signal, and V is the mirror velocity of the interferometer. After this interferogram is digitized, phase corrected, and Fourier transformed, one obtains the instrumental VCD (AC) transmission spectrum (Equation 11),

$$I_{AC}(\bar{\nu}) = \tfrac{1}{2}[I_R(\bar{\nu}) - I_L(\bar{\nu})] \exp(-2V\bar{\nu}\tau) \sin\alpha_M(\bar{\nu}) \qquad (11)$$

where the retardation angle of the PEM varies sinusoidally at the PEM frequency and is given by Equation (12):

$$\alpha_M(\bar{\nu}) = \alpha_M^0(\bar{\nu}) \sin 2\pi\nu_M t \qquad (12)$$

When the DC and AC transmission spectra in Equations (9) and (11) are ratioed, the result is proportional to the VCD spectrum of the sample, according to Equation (13):

$$\frac{I_{AC}(\bar{\nu})}{I_{DC}(\bar{\nu})} = 2J_1[\alpha_M^0(\bar{\nu})] \exp(-2V\bar{\nu}\tau) 1.15\Delta A(\bar{\nu}) \qquad (13)$$

Here the efficiency of the PEM at a particular wavenumber frequency is given by the first-order Bessel function, $J_1[\alpha_M^0(\bar{\nu})]$. The final VCD spectrum can be obtained after a VCD calibration spectrum is collected using a multiple waveplate with axes parallel or perpendicular to the stress axis of the PEM followed by a polarizer oriented parallel or perpendicular to the polarizer in Figure 1. There are four possible settings for the waveplate and polarizer, and the VCD intersection points of the curves they produce define a calibration plot given by Equation (14):

$$\left.\frac{I_{AC}(\bar{\nu})}{I_{DC}(\bar{\nu})}\right|_{CAL} = \pm 2J_1[\alpha_M^0(\bar{\nu})] \exp(-2V\bar{\nu}\tau) \qquad (14)$$

Division of this curve into the ratio in Equation (13) isolates the properly calibrated VCD spectrum $\Delta A(\bar{\nu})$. The phase correction used for the VCD interferogram to eliminate $\theta_{AC}(\bar{\nu})$ before Fourier transformation is obtained by a special procedure that requires the transfer of the phase correction from a monosignate VCD spectrum from a stressed optical plate. This is necessary

because the self-phase correction of the VCD spectrum using conventional FTIR software leads to sign errors when the raw VCD spectrum changes sign.

3.2 Examples of Vibrational Circular Dichroism Spectra

The VCD and IR spectra of (*s*)-(−)-α-pinene between 1350 and 800 cm^{-1} are presented in Figure 2. The spectrum was measured as a neat liquid with a 73 μm BaF_2 cell and the Chiralir™ VCD spectrometer. The VCD is half the difference between 20 minute collections of the (−) and (+) enantiomers as discussed further below. Above the VCD spectrum on the same intensity scale is the noise spectrum associated with the VCD spectrum. Note that the VCD spectrum is approximately four orders of magnitude smaller than the corresponding parent absorbance spectrum. Positive VCD bands, according to the definition of ΔA given in Equation (1), absorb LCP radiation more strongly than RCP radiation, and vice versa for negative VCD bands. The VCD spectrum of α-pinene is routinely used as an intensity standard and a basis for comparing the performance of different VCD instruments. This molecule can be sampled in high concentration as a neat liquid and has a rigid stereoconformation due to its fused ring structure. The VCD spectrum of α-pinene is relatively large and not difficult to measure with high signal quality.

A second example of a VCD spectrum is given in Figure 3 where the IR, VCD, and VCD noise spectra of L-valine in H_2O are presented. The spectra were measured on the Chiralir™ at a concentration of 250 mg mL^{-1} in aqueous HCl solution using a 12 μm path length cell. This is a more difficult case for two reasons. First, the

Figure 2 Absorbance (bottom), VCD (middle) and VCD noise (top) spectra of (*S*)-(−)-α-pinene as a neat liquid in a 73-μm BaF_2 cell. Collection time for each enantiomer is 20 min.

Figure 3 Absorbance (bottom), VCD (middle) and VCD noise (top) spectra of L-valine measured in H_2O/HCl solution at a concentration of 250 mg mL^{-1} and a path length of 12 μm. Collection time for each enantiomer is 1 h.

largest VCD features are 10 times smaller than the largest features for α-pinene and, second, the solvent absorbs some of the IR beam, thus reducing the amount of available IR radiation for measuring the VCD spectrum. Therefore, even though the VCD spectrum for L-valine was collected for 1 h, the signal-to-noise ratio (S/N) is lower than that observed for α-pinene in 20 min of collection. In the following sections we examine in further detail some of the more practical aspects of acquiring final calibrated VCD spectra.

3.3 Baseline Flatness and Stability

Because VCD signals are so small, the instrument baseline at the scale of VCD sensitivity may not correspond to true zero. In Figure 4, the VCD spectra of both enantiomers of α-pinene, and a third spectrum from a solution that is nearly the racemic mixture but still has a few percent of the (−) enantiomer present, are shown. This near racemic spectrum is very nearly the baseline of the empty instrument, and except for a few deviations where the spectrum has large VCD spectral features is identical, to within the noise of the true racemic VCD spectrum. Notice that all three curves pass through the common points where the VCD has a zero value. The baseline shown is relatively flat and close to the true zero of the instrument. Specifying the instrument baseline in the absence of a sample is a criterion for the quality of the VCD instrument. If little care is taken in the choice of optical elements or the alignment of these elements, poor VCD baselines with large deviations from zero on the VCD intensity scale may be encountered. The

Figure 4 The VCD spectra of (−)-, (+)-, and (±)-α-pinene, neat liquid, at 73-μm path length, showing opposite VCD for the (+) and (−) enantiomers, and a near racemic mixture exhibiting a slight percentage enantiomeric excess bias toward the (−)-enantiomer.

baseline in Figure 4 corresponds to a very good VCD baseline.

There are two principal sources of baseline deviations in the measurement of a VCD spectrum. One is the empty beam VCD baseline. This is the starting point of all VCD measurements. A second type of baseline deviation, or artifact, varies (in a complex way) with the absorbance of the sample. This second kind of artifact can be isolated, if it is present, by comparing the empty beam VCD spectrum, or the solvent VCD spectrum, with the VCD of the racemic mixture of the chiral sample under investigation. We make this comparison in Figure 5 for valine in H_2O, where in this case the empty beam includes the sample cell and H_2O solvent. The VCD spectrum of racemic valine should be zero since the sample has no net chirality. Inspection of Figure 5 reveals that the baseline VCD spectrum of the solvent and racemic valine are indeed very close and substantially within the noise level of the VCD measurement. Hence, there is only a baseline deviation of the first kind here, and this is easily removed by subtraction of the solvent VCD. If both kinds of baseline deviation were present, then the correct VCD spectrum could only be obtained by subtraction of the VCD spectrum of the racemic sample or, better still if available, the opposite enantiomer.

Although, it wasn't stated explicitly earlier, opposite enantiomers have opposite VCD spectra with respect to the baseline for the sample. This is illustrated in Figure 6 for L-valine and D-valine. The final spectrum in Figure 3 was obtained by subtracting the VCD spectrum of D-valine from that of L-valine and dividing by two. This subtraction removes all sources of artifacts. In many cases, however, both enantiomers are not available. For such cases, it is important that the VCD instrument is not sensitive to absorption artifacts, and ideally that the empty instrument or solvent artifacts are as small as possible.

Figure 5 Comparison of the baselines for the solvent H_2O (dashed) and racemic valine (solid) in H_2O/HCl showing that both are the same to within the noise level. Spectra were obtained under the conditions of Figure 3. Absorbance spectrum shown is for the raw DL-valine prior to water subtraction.

Figure 6 Comparison of the VCD spectra of L-valine and D-valine in H_2O/HCl prior to baseline correction. Spectra were obtained under the conditions of Figure 3. Absorbance spectrum shown is for raw L-valine prior to water subtraction.

It has been observed that absorption artifacts increase in importance (and annoyance) as the empty instrument baseline deviates more significantly from true zero.

The reliable subtraction of VCD spectra obtained from successive measurements, requires good instrument stability over the time of both measurements. Stability can be checked by running a series of VCD spectra to look for variations or baseline wander outside the expected

Figure 7 Superposition of 12 VCD spectra of (−)-α-pinene, neat liquid, for 20-min collection time per measurement.

noise level. This can be checked in several ways. One is to determine a noise curve for each VCD measurement that is the result of dividing the VCD collection into two successive blocks. Adding these blocks yields the final VCD spectrum and subtracting removes all the VCD features but leaves only the effects of noise and baseline instability. Examples of such noise curves are presented in Figures 2 and 3. From these the noise level across the spectrum is more apparent than it is in the spectrum itself, and second, the flatness and position of the noise curve at the zero level attests to the stability of the two measurements.

Another approach to testing VCD instrument stability is presented in Figure 7 where the results of 12 successive 20-min measurements of (−)-α-pinene are presented. The spectra were measured over a 4-h period without any interruptions or sample changes. A high level of reproducibility is observed with no systematic drift outside the noise level of the measurements. Below approximately 850 cm^{-1} the noise level increases owing to absorption in the beam from BaF_2 windows in the sample cell.

3.4 Intensity Calibration and Reproducibility

As mentioned above, Equation (14) describes a calibration curve obtained from the nonzero intersection points of a pair of VCD calibration curves. These intersection points and the resulting calibration represent unit VCD intensity at each wavenumber frequency. In Figure 8 the two curves are shown with their connected intersection points. The resulting calibration curve is shown for a setting of the PEM with maximum VCD efficiency near 1100 cm^{-1}. For the region near this frequency the calibration curve is nearly the same value. The decrease in VCD efficiency toward higher frequencies is the result of lower values of the Bessel function and the exponential lock-in decay factor which disadvantages higher frequencies.

Figure 8 The VCD waveplate curves and the VCD calibration curve derived from connecting intersection points on the waveplate curves.

Figure 9 Comparison of the absolute intensities of the VCD spectrum of (+)-α-pinene measured on the Chiralir™ at the University of Southern California (solid line) and a home-built instrument at Syracuse University (dashed line).

Presently, work is in progress to define an absolute intensity standard for VCD based on the spectrum of (−)-α-pinene. Spectra for this sample and one other have been obtained from a number of laboratories where VCD instruments are located. To illustrate the level of agreement obtained for two such instruments, Figure 9 shows VCD spectra of (−)-α-pinene from two laboratories, the laboratory of Philip Stephens at the University of Southern California using the Chiralir™ (solid line) and the laboratory of one of the co-authors at Syracuse University using a homebuilt VCD instrument based on Nicolet 850 spectrometer (dashed line). Both VCD spectra are presented in terms of the absorption coefficient, $\Delta\varepsilon$, to eliminate the effects of differing path length, and hence different Δ absorbance values, for the

two measurements. These two VCD measurements from instruments of different design are in relatively close agreement. Differences that do exist arise from variations in the way the calibration measurement was executed and possible errors in the path lengths of the cells used. It is expected that with sufficient care, agreement for the absolute intensity values of the (−)-α-pinene VCD spectrum in the mid-IR region can be determined to within a few percent. Once this has been accomplished, a new way to calibrate VCD, namely relative to the (−)-α-pinene spectrum, can be established.

3.5 Signal-to-noise Ratio

An important variable in the measurement of VCD spectra is the S/N. All VCD spectra, no matter how large, take longer to acquire than the corresponding FTIR absorbance spectra. The disadvantage of four orders of magnitude is overcome in part owing to the sophisticated electronic pathway that permits isolation and amplification of the VCD signal independently of processing the ordinary IR spectrum. The VCD spectra are generally too small to obtain by simply obtaining the absorbance spectra of LCP and RCP separately and subtracting.

To obtain a VCD spectrum at the desired S/N, one needs to decide how long to collect the spectrum. Figure 10 shows the VCD and noise spectra for a single enantiomer, with no baseline correction, of (−)-α-pinene after 1 min of collection, 5 min of collection, and 20 min of collection. Dramatic increases in the S/N can be seen. The general rule of signal averaging for FTIR and FT/VCD is that the S/N improves as the square root of the increase in time of collection. Thus the 5 min scan has lower noise than the 1 min scan by a factor of $1/\sqrt{5}$, and the improvement gained in collecting for 20 min instead of 5 is a factor of 2. For long scans it advisable to collect the spectra in blocks, say 1 h each, so that if the liquid nitrogen runs out, the sample degrades, or some undesired change in the measurement occurs, the prior blocks of data will be available and safe.

Figure 10 The VCD spectra and noise curves (above) for (−)-α-pinene under the sampling conditions of Figure 2 for collection times listed showing improvement in spectral quality with increased collection time.

4 BIOLOGICAL EXAMPLES

Naturally occurring biological molecules of all varieties can be measured by VCD. These include amino acids, as illustrated above in the case of L-valine, peptides, proteins, nucleic acids, and sugars. This section provides further examples of biological molecules of several classes. An important issue to resolve for the sampling of any biological sample is the solvent. Water (H_2O or D_2O) is an important solvent for biological samples. All but a few solvents have regions of intense absorption in particular regions of the mid-IR. A useful preliminary exercise when considering a solvent is to measure the transmission spectrum of the pure solvent near the path length of interest for the sample measurements. In Figure 11 the transmission spectra for H_2O and D_2O are presented where, for the sake of direct comparison, a path length of 12 μm is used for both solvents. In practice, shorter path lengths are generally used for H_2O and longer ones for D_2O.

4.1 Proteins

Proteins exhibit strong VCD in the amide I and II regions of the IR spectrum, and the chirality of the constituent amino acids drives the overall sense of the helical structure.[20,21] In Figure 12 four examples of protein VCD are shown. In Figure 12(a) and 12(b) the VCD

Figure 11 Percentage transmission spectra for H_2O (solid) and D_2O (dashed) at a path length of 12 μm.

Figure 12 Absorbance and VCD spectra in the amide I and II regions for two proteins: (a) hemoglobin in H_2O, (b) chymotrypsin in H_2O, (c) hemoglobin in D_2O, and (d) chymotrypsin in D_2O. Spectra in H_2O were measured at a concentration of 150–200 mg mL^{-1} and path lengths of 4–6 μm and spectra in D_2O were measured at a concentration of 20 mg mL^{-1} and 80-μm path lengths.

and IR spectra for hemoglobin and α-chymotrypsin in H_2O, respectively, are presented, and the corresponding spectra in D_2O are given in Figure 12(c) and 12(d). The measurements were made with the Chiralir™ at a spectral collection time of 1 h for hemoglobin and 3 h for chymotrypsin at a resolution of 8 cm^{-1}. For the H_2O measurements the protein concentrations were quite high at 150–200 mg mL^{-1} and correspondingly small path lengths of approximately 4–6 μm. For the D_2O measurements the concentration was lowered by a factor of 10, down to the biologically more relevant value of 20 mg mL^{-1} and the path length was increased to 80 μm. The absorbance spectra in all cases are corrected for solvent absorption, and the two prominent bands, near 1650 cm^{-1} and 1530 cm^{-1} are the amide I and II bands, respectively. In D_2O, small changes occur in the amide I region and the amide II band shifts to lower frequency, near 1450 cm^{-1}, although some unexchanged amide groups still remain. The secondary structure of hemoglobin under these conditions is predominantly α-helix, whereas the structure of α-chymotrypsin is primarily β-sheet. Both the VCD and IR spectra provided here

are typical for proteins with this secondary structure, and the distinct differences in these two cases reflect the sensitivity of VCD to the conformation of protein structure.

4.2 Nucleic Acids

Nucleic acids are chiral by virtue of the sugar–phosphate backbone which in turn drives the helical structure of the entire molecule. The VCD technique is sensitive to all regions of nucleic acids,[22] and in particular to the base stacking regions between 1750 and 1550 cm^{-1}. In Figure 13, the VCD and IR spectra of salmon sperm DNA dissolved in D_2O is presented. Under these conditions, the DNA helix is in the B-form conformation. The measurements were made with the Chiralir™ at a spectral collection time of 2 h at a resolution of 8 cm^{-1}. The concentration of DNA was 15 mg mL^{-1} and the path length was 75 μm. The VCD and IR spectra were corrected by subtraction of the corresponding background D_2O spectrum.

4.3 Sugars

Sugars have multiple centers of chirality and exhibit strong VCD spectra. Their conformation is easily studied in a variety of solvents. In Figure 14, the VCD and IR spectra of α-D-glucose in dimethylsulfoxide-d_6 (DMSO-d_6) is presented.[23] The solvent VCD and IR background spectrum were subtracted to obtain the result presented. The lower spectral limit is 1100 cm^{-1} because the solvent absorbs strongly below that point. The concentration used was 0.5 M or 90 mg mL^{-1} and the path length was 70 μm.

Figure 13 Absorbance and VCD spectra of salmon sperm B-DNA in D_2O solution at a concentration of 15 mg mL^{-1}, 75 μm path length, 2-h collection time.

Figure 14 Absorbance and VCD spectra of α-D-glucose in DMSO-d_6 solution at a concentration of 90 mg mL^{-1} and a path length of 70 μm.

The spectral collection time was 3 h using the Chiralir™ VCD spectrometer at Vanderbilt University. The VCD from sugars have strong contributions in the mid-IR from modes associated with C–O and C–C stretching and various bending modes.

5 PHARMACEUTICAL EXAMPLES

Increasingly the development of chirally pure pharmaceutical molecules is gaining importance. These molecules offer a rich variety of structural motifs for intended purposes in many different areas of application. In this section, two examples of chiral pharmaceutical molecules are provided as examples of the structure complexity in this class of molecules. The VCD and IR spectra are equally varied and offer the prospect of studying and specifying the stereochemistry of these interesting molecules.[24]

Ibuprofen is a common over-the-counter analgesic molecule. The VCD and IR spectra of (*R*)-(−)-ibuprofen are presented in Figure 15 in the region between 1600 and 800 cm^{-1}. The spectrum was obtained using a 75-μm cell at 4 cm^{-1} resolution on the Chiralir™. The collection time was 1 h per enantiomer where the final spectrum is half the subtraction of the two enantiomers. Ibuprofen was sampled as a solution in $CDCl_3$ at a concentration of 250 mg mL^{-1}. The absorbance spectrum was corrected for solvent absorption.

As a second example, the VCD and IR spectra of (*R*)-warfarin in $CDCl_3$ are presented in Figure 16. The spectra

Figure 15 Absorbance (bottom), VCD (middle), and VCD noise (top) spectra of (*R*)-(−)-ibuprofen in $CDCl_3$ at a concentration of 250 mg mL^{-1}, path length of 75 μm and a collection time of 1 h for each enantiomer.

Figure 16 Absorbance (bottom), VCD (middle), and VCD noise (top) spectra of (*R*)-warfarin in $CDCl_3$ at a concentration of 8.6 mg mL^{-1}, path length of 500 μm and a collection time of 3 h for a single enantiomer.

were measured on the Chiralir™ at 4 cm^{-1} resolution as a single enantiomer in a 3 h collection period. The concentration of the sample was 8.6 mg mL^{-1} at a path length of 500 μm. The VCD intensity in this spectrum is approximately 10 times smaller than that of α-pinene as can be discerned from the VCD intensity scale for similar IR absorbance intensities. This demonstrates that molecules with relatively small VCD can still be measured with good signal quality. Note the richness of the vibrational band structure for this molecule across a wide range of frequencies.

6 AREAS OF APPLICATION

VCD, and ROA, can be used for a wide variety of stereostructural analyses. The applications of VCD fall into three areas. The first is conformational analysis, and we have seen in the previous figures examples of VCD spectra where the principal objective in obtaining the spectra has been to study the solution conformations of the selected biological molecules. This is the oldest and most basic use of VCD spectra. Since the mid 1970s, VCD has been used as a research tool in academia to study the conformational properties of molecules where the absolute configurations were well known and the optical purity was assumed to be as high as possible, typically near 100%.

The other two areas of application of VCD are more practical and have come to the fore with the increasing interest by the chemical and pharmaceutical industries in the potential of VCD for determining the optical purity of manufactured samples and the absolute configuration of new chiral molecules intended for medicinal application. This section provides examples of the use of VCD in these two areas.

6.1 Enantiomeric Excess

Prior to VCD there were primarily three techniques used for the determination of enantiomeric excess. The oldest method is the measurement of optical rotation. If the rotational angle for the pure compound is known, measurement of the optical rotation provides a measure of optical purity. The principal shortcomings of this methods are that, first, only one spectral datum is associated with the measurement and, second, the value is very sensitive to the density of the sample and hence its temperature. Optical rotation has been replaced over the years by two new techniques. One is NMR shift reagent measurements and the other is chiral chromatography. In the NMR method, a chiral NMR shift reagent is added to the sample as a perturbant. Opposite enantiomers in the sample will experience shifts in some of their NMR resonances in opposite directions, and the areas of these shifted bands can be compared to determine the relative percentages of the two enantiomers. The drawbacks here involve finding suitable shift reagents, and difficulties arising when multiple chiral centers are present. In addition, the sample is altered in the process of measurement. In chiral chromatography a physical separation of the two enantiomers is effected by a chiral substrate in a column. If

the relative areas in the separated bands from the column are measured then the optical purity can be determined. The accuracy of this method for favorable cases is in the range of 0.1% enantiomeric excess. The percentage enantiomeric excess is defined as the difference in the measured quantities for two enantiomers divided by their sum and multiplied by 100. The principal difficulties in chiral chromatography are the time and expense of finding an efficient chiral substrate and maintaining the column.

VCD offers an alternative to these methods that has certain advantages, with some disadvantages. As shown above, VCD spectra have multiple bands that permit multiple points of chiral interrogation of the sample. Unlike optical rotation, VCD measurements are not particularly sensitive to temperature, and any changes in density that do occur are not multiplied by long path lengths and can be cancelled with the same changes that occur in the parent IR spectrum. In contrast to NMR shift reagents no foreign additive to the sample is needed to make the measurement and, further, no physical separation of enantiomers is required as is the case for chiral chromatography. One merely needs a good IR spectrum and a VCD instrument. The sample may be recovered entirely from the measurement. With appropriate sampling techniques, it should be possible to use VCD with multiple sampling or even flow sampling techniques. The principal disadvantage of VCD is the practical limit of approximately 1–0.5% ee obtained to date; however, improved techniques using chemometric methods are being developed.

An example of the use of VCD for a relatively difficult sample is given in Figure 17. Here are shown a set of VCD spectra for L-valine in HCl/H_2O in the region 1400–1200 cm^{-1} measured with the Chiralir™. Two bands are used for analysis, but many data points across each spectral curve are used in the determinations. The solutions were prepared by volumetric quantitative methods to be 100, 90, 80, 60, 40 and 20% ee. The VCD

Figure 17 The VCD spectra of L-valine in H_2O/HCl under conditions of Figure 3 for single enantiomer at percentage ee values of 100, 90, 80, 60, 40, and 20.

data were fitted to these known values using partial least squares (PLS) analysis and the optimized values obtained for these samples, as determined by VCD, were 100.5, 88.5, 78.5, 59.6, 44.3, 18.5% ee. The error range for these six determinations is 0.4–4.3% and the standard error (the square root of a result of 5 divided into the sum of the squares of the errors) is 2.26%. Unknown errors may also be present in preparation of samples, although they are presumed to be smaller than VCD spectral determination of percentage ee. Samples with higher intrinsic noise levels have produced errors as low as 0.4% ee, but the case here may be a more typical result. Thus VCD is available as a straightforward method with which to reliably determine percentage ee under a variety of nonperturbing sampling conditions. If only a qualitative monitor of the percentage ee, say to within 2% ee, and the sample integrity were desired, results could be available off-line on a 10–20 min cycle time or less depending on the S/N of the VCD measurement.

6.2 Absolute Configuration

Presently, there is only one conventional spectroscopic method for the determination of the absolute configuration of an unknown chiral molecule without reference to a prior structure or correlation. That is single-crystal X-ray diffraction. For this method the molecule of interest must form a pure single crystal of sufficient size for the X-ray analysis. In most cases use of a heavy atom crystal dopant is necessary to establish the absolute phase, and hence the absolute stereochemistry.

VCD now offers a viable alternative to X-ray analysis. As VCD spectra are usually measured in the solution phase, it is not necessary to grow a crystal or dope the crystal for analysis. The absolute stereochemistry is established by comparing the solution-phase VCD spectrum to the results of an ab initio quantum chemistry calculation. The absolute configuration used for the calculation is known. If the measured VCD agrees with the theoretical spectrum, the absolute configuration of the sample molecule is the same as that calculated, and if the experimental signs are opposite to the corresponding theoretical ones, so then is the absolute configuration of the sample molecule. In addition to this definitive method of determination of absolute configuration without reference to a standard compound, VCD can be used empirically to show the stereochemical relationship between two closely related molecules.

In principle, electronic CD could also be used in the same way for absolute configuration determination; however, there are several difficulties. First, there are usually only a few bands rather that a dozen or so for points of comparison. Second, calculating the electronic CD spectrum requires good quantum mechanical descriptions of both the ground and the excited electronic states,

whereas only the former is needed for VCD calculations; VCD arises from only the vibrational modulation of the ground electronic state and is not a two-electronic-state phenomenon. It is well known that excited electronic states are much more difficult to calculate than the corresponding ground electronic state. Finally, not all molecules have electronic states in the accessible region of the electronic spectrum, as is the case below.

In Figure 18, the calculated and observed VCD and IR spectra for (*S*)-(−)-*trans*-pinane is shown. The absolute stereochemistry of this molecule is also displayed in the figure. Note that the molecule is a pure hydrocarbon and has no functional groups. Hence its electronic CD spectrum would be difficult, if not impossible, to measure with a conventional electronic CD instrument. Inspection of the figure reveals a high level of agreement, both in signs, relative magnitudes, and absolute magnitudes of all the bands. No adjustable parameters were invoked in the calculation, only a choice of bandwidth for the theoretical intensities. The experimental spectrum was obtained with the Chiralir™ from a neat liquid using a path length of 55 μm and 4 cm^{-1} resolution. The theoretical spectrum was obtained using the commercial software program Gaussian 98 using density functional theory, a 6-31G(d) basis set, B3LYP hybrid functionals, 54 h of cpu time for the frequency and VCD calculation on a Silicon Graphics SGI-02 workstation. Because this molecule is rigid, the determination of the equilibrium conformation is simplified to one conformer, but absolute configuration determination by VCD has been successfully demonstrated for cases where more than one conformer is important or potentially important.

Figure 18 Comparison of the absorbance and VCD spectra of (*S*)-(−)-*trans*-pinane for experimentally measured (observed) and theoretically predicted (calculated) spectra.

7 CONCLUSIONS

VOA, consisting of IR/VCD and vibrational ROA, has evolved to a point of routine stereochemical application. This article has introduced the basic principles of these two closely related techniques and has illustrated the principal areas of application of VCD, namely conformational analysis, optical purity measurement, and absolute configuration determination. The availability of commercial instrumentation for VCD such as the Chiralir™ from Bomem/BioTools and ab inito molecular orbital software for VCD intensity calculation in Gaussian 98 from Gaussian Inc. have hastened the advance of VCD for widespread application beyond the laboratories of the VCD specialists. Similar advances will eventually be made for ROA, and then both approaches to VOA will be available for broad use in the study of chiral molecules.

The mammalian brain is the most complex structure known to science. Our behavior, feelings, thoughts, and maybe even consciousness itself, may be a reflection of the interplay of electrical and chemical signaling that create these states, and how the physical brain gives rise to the properties of mind remains a major unanswered question. It is clear, however, that many of the drugs used empirically in the treatment of neurological disorders, such as Parkinson's disease, schizophrenia and depression, as well as mind-altering substances of abuse, have specific chemical actions on nerve cells in the brain, highlighting the importance of chemical signaling in the functioning of neural networks.

A growing number of methodologies are being developed, including sampling, spectroscopic and electrochemical, to study neurochemical phenomena in the living brain. One such set of techniques focuses on the detection of substances released from nerve cells, using amperometric electrodes and voltammetry in vivo (VIV) techniques. By implanting a microvoltametric electrode in a specific brain region, applying a suitable potential profile and recording the resulting faradaic current, changes in the concentration of a variety of substances in the extracellular fluid (ECF) can be monitored with sub-second time resolution over extended periods. This allows investigations of the functions and roles of specific neurochemicals in neuronal signaling, drug actions, and well-defined behaviors. The main limitations associated with VIV is, on the one hand, the limited number of ECF species that are electroactive, and on the other, the fact that electroactive substances present tend to oxidize at similar potentials, interfering with each other's detection. These restrictions are being overcome by ongoing developments, including the design of biosensors to broaden the range of target analytes and permselective membranes to block interference.

1 INTRODUCTION

1.1 Intact Brain Preparation

Mammalian behavior is a reflection of the activity of the central nervous system (CNS), and in particular the brain. The brain is adept in a wide range of functions, including: sensory input and processing; behavioral output or response; subtle colorings of the animal with feelings such as depression, anxiety and reward; memory; and in higher animals it is involved in phenomena such as language and imaginative thought.[1]

The substrates of these diverse functions are complex networks of complex units – nerve cells or neurons. Each neuron consists essentially of a cell body from which extend a large number of cytoplasmic projections. One of these projections, the axon, is usually much longer than the others, and may bifurcate several times; the remaining, smaller, extensions are the dendrites. The ends of the axon (nerve terminals) are normally swollen and contain specialized organelles for storing chemical messengers. Most neurons are electrically isolated from each other, and form networks by interfacing through anatomically well-defined gaps (synapses), usually between the terminal of one neuron and the cell body or dendrites of another (Figure 1).

Although the processing of electrical signals may be considered the primary function of nerve cells in the brain,[2] intercellular chemical signaling plays a major role in determining the properties of neural networks. The individual nerve cells normally communicate their state of excitation or inhibition to other neurons by releasing chemical messengers across their synapses, and the CNS uses a wide variety of intercellular chemical messengers (neuromediators) in synaptic signaling. (The term neuromediator is used here to include classical neurotransmitters, neuromodulators and neurohormones.) In addition, each released neuromediator substance can bind to a range of different receptor proteins embedded in the membrane of the target cell. Some receptors (ionotropic), when activated, open ion channels that lead to millisecond changes in the electrical potential across the membrane. Others (metabotropic) are linked to enzymes located on the intracellular side of the membrane; when activated these receptors can either accelerate or inhibit the production of intracellular 'second messenger' systems that can change the condition of the target neuron over extended periods of time. This combination of diverse neuromediators, receptors and mechanisms of interaction are some of the factors that enable the CNS to function over a vast spectrum of timescales, producing responses ranging from reflex actions to memories lasting many decades.

Figure 1 shows a schematic representation of intercellular chemical signaling at a synapse between a nerve terminal and target neuron. In the resting state, the nerve cell membrane (lipid bilayer containing a variety of attached and transmembrane proteins) is polarized at about −70 mV (negative on the inside) due to a transmembrane concentration gradient of K^+ (high inside) and the presence of K^+-selective

Figure 1 Schematic representation of intercellular chemical signaling at a synapse between a nerve terminal and target neuron. Neuromediator substance (T); precursor of T (P); enzymes involved in the synthesis of T (ENZ-SYN); vesicles for storing T (V); metabolites of T (M); enzymes involved in metabolism of T (ENZ-MET); action potential (AP); ion channels (IC); receptor complexes (R); second messenger enzyme (ENZ-SM); ion-coupled carrier uptake sites (U). For dopamine (DA)-releasing terminals in the striatum, nucleus accumbens and frontal cortex that have been the subject of many VIV studies, the following neurochemistry is involved. The precursor amino acid tyrosine is converted to 3,4-dihydroxyphenylalanine (DOPA) in the rate-determining synthetic step by tyrosine hydroxylase and then to DA by DOPA decarboxylase. The presynaptic metabolic enzyme is monoamine oxidase (MAO) (type A, MAO-A) that acts on DA to produce 3,4-dihydroxyphenylacetic acid (DOPAC). Both DA and DOPAC can be metabolized outside the terminal (on the postsynaptic membrane and in glial cells) by catechol-*O*-methyl transferase (COMT) to produce 3-methoxytyramine (3MT) and homovanillic acid (HVA) respectively. Because 3MT has a higher affinity for the DA uptake carrier than DA itself,[29] it is not surprising that the bulk of 3MT is further degraded by MAO to yield HVA, so that DOPAC and HVA are the main DA metabolites found in the ECF. The main presynaptic DA receptor is the D-2 receptor, linked to adenylate cyclase. Activation by DA leads to a decrease in the level of cyclic adenosine monophosphate (cAMP) in the terminal, an inhibition of Ca^{2+} release from intracellular stores, and the opening of K^+ channels, leading to hyperpolarization; two principal effects of these changes are a decrease in the activity of tyrosine hydroxylase lowering the synthesis rate of DA, and a decrease in DA release (negative feedback). The postsynaptic D-1 receptor is also linked to adenylate cyclase, but here activation by DA leads to stimulation of cAMP production. (Adapted from O'Neill[13] with permission from Royal Society of Chemistry.)

ion channels that are permanently open (leakage channels).

A precursor, such as an amino acid, is taken from the ECF into the terminal where one or a number of enzymes transform it into the neuromediator substance characteristic of the particular neuronal pathway. Although most of the newly synthesized neuromediator is taken up into storage vesicles, some will be inactivated before reaching the vesicles by metabolic enzymes present in the terminal. When an action potential (rapid depolarization, followed by repolarization of the membrane potential; total duration about 5 ms) propagates down an axon to the nerve terminal, voltage-sensitive Na^+ ion channels open, causing depolarization of the terminal membrane and the opening of voltage-sensitive Ca^{2+} channels, the influx of Ca^{2+}, and ultimately to the fusion of vesicles that release their neuromediator content into the synapse; a few milliseconds later, the opening of voltage-sensitive K^+ channels results in repolarization. This Ca^{2+}-dependent exocitotic release of neuromediator is surprisingly fast, occurring within microseconds of the start of the action potential in the terminal.[3]

Once in the synapse, the neuromediator molecules may bind to a range of different receptor proteins on either the presynaptic or postsynaptic membrane. On the presynaptic side, receptors may be linked to a 'second messenger' enzyme involved in regulating the activity of the rate-determining enzyme used in the synthesis of neuromediator (negative feedback control). Postsynaptically, receptors may also be linked to a second messenger system or to ion channels for Na^+, K^+, Ca^{2+} or Cl^- that control the membrane potential of the target neuron. Inactivation of the chemical signal is achieved either by re-uptake of neuromediator into the terminal (and other sites, such as glial cells) through specific ion-coupled carrier uptake sites (also capable of releasing cytoplasmic neuromediator by a Ca^{2+}-independent mechanism) and subsequently metabolized, or may be metabolized extracellularly. The metabolites can diffuse into the ECF that also contains small concentrations of neuromediator that overflow from the synapse. The concentrations of metabolites and neuromediator in the ECF can also be regulated by the rate of their excretion into the cerebrospinal fluid or across the blood–brain barrier (BBB).

One of the key elements in understanding the role of each neuromediator substance in neural networks is a knowledge of release rate, and Adams et al.[4] suggested that voltammetric electrodes implanted directly in the intact brain might be used to monitor electroactive neuromediators in the CNS (see section 2). However, electrodes generally employed for neurochemical analysis using VIV are ~5–300 μm in diameter and monitor an average concentration of analyte in the medium surrounding cells, the ECF, and not directly in synapses that are orders of magnitude smaller (typically 20–30 nm from terminal to target, see Figure 1). It is not clear at present what the relationship is between release of different neuromediators into the synapse and resulting ECF levels, although balance between release and re-uptake (Figure 1) is involved. It is also debatable whether neuromediators released into a synapse have additional extrasynaptic functions, so that the synapse might be designed to 'leak'. For example, extrasynaptic receptors have been reported for the main excitatory CNS neuromediator, glutamate,[5] as well as evidence for the diffusion of neuromediators, such as glutamate, outside the synaptic cleft.[6] An additional factor is that some neuromediators, such as norepinephrine (NE), are not released into anatomically well-defined synapses, but from simple swellings along the axon, so that their sphere of influence may extend far (up to 100 μm)[7] into the ECF.

Neuromediators and their metabolites in the ECF have been studied using VIV and a variety of perturbations that fall into two main categories (see Figure 1): those that cause depolarization of the terminal, including electrical stimulation, application of extracellular K^+, administration of agents that bind to receptors linked to ligand-gated Na^+ channels (e.g. glutamate), and behavioral activation (e.g. tail pinch); and those that cause changes in ECF levels by mechanisms not involving depolarization directly, such as inhibition of synthesis (e.g. α-methyl-*p*-tyrosine), displacing neuromediators from the terminal (e.g. amphetamine), inhibition of metabolic enzymes (e.g. pargyline), or blocking re-uptake (e.g. cocaine). A number of reviews on the principles and applications of voltammetric analysis of the ECF have been published, and a representative selection is cited here.[8–22] Original forms of some of the concepts presented in this article can be found in previous reviews.[13,19,21]

1.2 Other Brain Preparations

As a complementary approach to voltammetric recording in the living brain, the brain slice preparation has proved useful for studying the properties of individual neural pathways using voltammetric techniques.[15,20,22–25] A slice of brain containing the projection of interest (often the dopaminergic nigrostriatal system) is maintained in a physiological medium in vitro. This allows direct manipulation of the pathway with, for example, electrical or chemical stimulation, and the application of drugs affecting release, such as neuromediator synthesis inhibitors and receptor ligands (Figure 1), with reproducible results reported for up to 9 h.[26] Details of this preparation are given in article: **Neurotransmitters, Electrochemical Detection of**.

Pioneered by Schenk et al.,[27] another preparation of brain tissue, that has been used in voltammetric studies in vitro, is obtained by dissecting a particular brain region (usually the striatum) followed by its disruption, using a rotating disk electrode (RDE), to produce a suspension of whole tissue. With the RDE held at a constant potential to detect neuromediators, analogs or other agents added to either this suspension or the more classical synaptosomal preparation of striatal tissue, the mechanism of DA uptake,[28] ligand structure/activity relationships[29] and interactions with drugs of abuse[30] have been studied.

Understanding the functioning of brain neurons can also be advanced by studying the properties of other cell types[31–33] and peripheral neurons[34–38] isolated in vitro. Investigations of the chemistry within the cytoplasm of individual cells in vitro are now possible using submicron carbon ring, carbon fiber or Pt electrodes,[39–41] and intracellular Ni^{2+},[42] oxygen,[43] DA[44,45] and serotonin[46] have been monitored electrochemically. The majority of voltammetric reports on the behavior of isolated cells, however, have concentrated on the mechanism of release of catecholamines from adrenal medullary chromaffin cells[47–49] and serotonin from mast cells,[50,51] and signals associated with the release of neuromediator from single vesicles have been described.[32,47,52,53] Recent work on the release of peptide hormones from single cells has also been reported.[54,55]

1.3 Legal and Ethical Considerations

Legislation controlling the use of animals in scientific experiments varies from country to country, with some countries having strict legal requirements and others having poor, or in some cases no, legislation. For example, in the United Kingdom, legislation is enforced by the Home Office and is covered by the Animals (Scientific Procedures) Act 1986. The latter operates on a dual licence system: a personal licence for individual workers, specifying procedures and types of animals that may be used according to competence, training, qualifications and experience; and a project licence covering each specific programme of work. In the United States, the system is generally based on institutional licences being required for all projects and procedures. Large funding agencies for biomedical research, such as The Wellcome Trust (UK) and the National Institutes of Health (USA), also have very specific regulations concerning the welfare of animals and proper codes of practice. In addition to national legislation and institutional requirements, there are also international laws, such as European Directive 86/609/EEC, relating to the protection of animals used for experimental and other scientific purposes. Generally, all such policies are designed to control procedures that may cause pain, suffering, distress or lasting harm to animals used in scientific procedures. Provisions generally cover several areas, including a specification of the programme of work, the purpose and scientific justification for the work, a full description of the procedures involved (experimental protocol), the types of animals to be used, and an assessment of the potential severity of each procedure and the scientific programme as a whole.

The ethics of using animals in scientific experiments has become a very important issue. All use of animals in research for human benefit creates a dilemma; the justification for using the animal depends on it being different from the human, while the validity of the results obtained depends on the similarity of the animals, and their responses, to those of the human. Important considerations are:

- Can one justify what one is doing and does the potential benefit derived from the results outweigh the value of the animal? Potential benefit must be weighed against any pain, suffering (e.g. isolation or confinement) or lasting harm that may be caused to the animals used.
- Is it possible to achieve the same benefit by either carrying out an in vitro experiment, using a mathematical model, or using a different animal species lower in the phylogenetic scale?
- Can one use fewer animals by better experimental design, or by collaborating with colleagues so that as many tissues as possible from each animal are utilized?
- Can one alter the experimental method in some way to decrease the animal's potential suffering, for example, by an alteration in surgical technique, improvements in housing or bedding or by altering the drug dosage regime for a reduced volume or reduced frequency?

The last three considerations are often referred to as 'the three Rs' (replacement, reduction, and refinement) and form the backbone of any ethical review of animal research. Since this section is intended only to provide general guidelines relating to legislation and the ethics of using animals, the reader is urged to consult and examine texts for a more detailed consideration of the law and the ethics of animal use before embarking on such research.[56–58]

2 HISTORY

Although reports of voltammetry in the living brain go back at least as far as 1958 when Leland C. Clark demonstrated the feasibility of voltammetric recording in brain tissue in vivo for oxygen and ascorbic acid (AA)

detection,[59,60] the concept of applying voltammetric techniques to monitor changes in the concentration of electroactive neuromediators in brain ECF is generally attributed to Ralph N. Adams et al.[4] The paper describes attempts to detect neuromediator DA in anesthetized rat brain, using a carbon paste electrode (CPE) and cyclic voltammetry (CV). Even at this early stage, the authors successfully identified many of the problems and factors affecting the shape of voltammograms recorded in brain tissue. Thus, reference is made to depletion of the ECF around the electrode by the scan leading to thin-layer behavior, tortuous diffusion in the tissue, heterogeneous distribution of target analytes in various compartments in the brain, overlap of different signals, and perturbation of the tissue by the implanted electrodes. Quite inspirationally, the authors also suggested a number of strategies to address some of these problems, such as the use of permselective membranes and immobilized enzymes, tactics that proved successful many years later.

2.1 Original Interference Problem

Despite the aim to detect neuromediator DA in this first study using VIV, Adams et al.[4] concluded correctly that the voltammograms recorded were due to a number of different compounds present in the ECF, oxidizing at similar potentials at the CPE, and that AA, not DA, was the principal contributor. The initial success, however, was soon undermined by a widespread assumption that the concentration of AA in brain ECF was essentially constant. This led to conclusions that changes observed in the voltammetric signal were due to other species such as DA and serotonin. It was not until the early 1980s that this assumption had to be abandoned when two independent studies[61,62] showed that systemic administration of a commonly used DA-releasing drug, amphetamine, also caused changes in the concentration of AA in brain ECF.

Having established that ECF brain AA concentrations respond to a wide variety of stimuli, including pharmacological, electrical and behavioral (see section 7.3 and review by O'Neill[63] for details), efforts began in earnest to resolve the different contributions present in brain voltammograms. Two basic approaches have been used: eliminating undesired signals (e.g. those of AA and neuromediator metabolites), principally by means of chemical modification of the electrode surface; and separating the voltammogram components into identifiable signals using a combination of surface modification, applied potential waveforms, and mathematical analysis of the current; examples of validation of specific sensors are described in section 4. These developments in VIV over the past two decades have led to its establishment as a valuable tool in many aspects of neuroscience research, including anatomical, pharmacological and behavioral studies.[8–22]

2.2 Analytical Problems of Voltammetry In Vivo

It should be stressed that the application of VIV involves far more than a straightforward transfer of expertise gained from the practice of voltammetry in vitro. In addition to being anatomically complicated and containing a wide range of electroactive substances, brain tissue presents a complex chemical environment that includes surfactants (lipids), electrodes poisons (proteins), electrocatalysts such as glutathione and AA, and a tissue matrix that both restricts mass transport to the electrode surface and reacts physiologically to the presence of the probe.[64] Thus, the behavior of a particular electrode and voltammetric technique in vitro might well be different to its behavior in vivo, because both modification of the electrode surface by components of the tissue,[65] and the differences in mass transport,[66–69] could lead to different responses (sensitivity, selectivity, stability, etc.) in the two environments.[70] Therefore, detailed characterization in vitro of parameters such as detection limits is of little use, and may be misleading in an application like VIV where the major issue is that of selectivity rather than sensitivity.

Indeed, the complexity of the system is such that some forms of VIV may have been characterized in error in the literature, and subtle differences in methodologies might lead to an inability to reproduce reported characteristics. It is advisable, therefore, that each laboratory

Table 1 Electrochemical and concentration data for the most common species detected voltametrically or amperometrically in brain ECF

Compound	Charge[a]	$E_{1/2}$ versus SCE[b]	ECF concentration[c]
AA	−	−100 to 400	100–500 μM
DA	+	100 to 250	1–50 nM
NA	+	100 to 250	1–50 nM
DOPAC	−	100 to 250	1–20 μM
5HT	+	300 to 400	1–10 nM
5HIAA	−	300 to 400	1–10 μM
UA	−	300 to 400	1–50 μM
3MT	+	500 to 600	<1 μM
HVA	−	500 to 600	1–10 μM
NO	0	−900 and +1000	10–100 nM
O_2	0	−400 to −600	40–80 μM
Glucose	0	enzyme catalyzed	0.5–2 mM
Lactate	−	enzyme catalyzed	0.5–2 mM
Glutamate	−	enzyme catalyzed	1–10 μM

[a] At physiological pH (7.4).
[b] Very rough guide; depends on electrode material and its state of activation.
[c] Very rough guide of nonstimulated mean values; depends on animal species, brain region and level of anesthesia; values most appropriate for rat striatum.
5HT, 5-hydroxytryptamine; 5HIAA, 5-hydroxyindoleacetic acid; NO, nitric oxide; SCE, saturated calomel electrode; UA, uric acid.

considering adopting VIV, having decided on the form that promises to be suitable for the neurochemical study in question, should either characterize the technique in detail in vivo or, at least, test it with a series of well-documented pharmacological challenges. For example, a sensor designed to detect striatal DA must be relatively unresponsive to other ECF species, especially AA and catechol metabolites (see Table 1). The first selectivity test should be against AA, because of its several thousand-fold excess over DA in brain ECF. This selectivity can be ascertained by, for example, systemic administration of a DA-receptor agonist, such as apomorphine, that causes decreases in striatal ECF DA levels while increasing those of striatal AA.[71] If the sensor passes this test, then systemic administration of a MAO inhibitor (see Figure 1 legend), such as pargyline or amphetamine, can be used to test selectivity for DA versus catechol metabolites by increasing the concentration of DA in the ECF and decreasing catechol metabolite levels.[61,72] Note, however, that this second test can only be interpreted correctly if the sensor has passed the first selectivity test, because drugs like pargyline and amphetamine also cause increases in striatal AA concentration in the ECF.[61,62,72] The route of drug administration in these tests is also important. Particularly, systemic injection of drugs (intraperitoneally, subcutaneously, etc.) can have very different effects compared with their local perfusion directly into the brain.[62,73] An additional precaution is that of timescale. A technique demonstrated to detect DA selectively on a fast timescale (seconds) cannot be assumed to do so on slower timescales (minutes) because changes in neuromediator concentrations tend to be much faster than those of their metabolites.[74] These points will be developed below.

3 SUBSTANCES TARGETED WITH VOLTAMMETRY IN VIVO

One of the main problems associated with producing identifiable voltammetric signals directly in vivo is that the ECF contains a wide variety of electroactive species that oxidize at similar potentials on many electrode materials. Moreover, baseline ECF concentrations of the main target molecules – neuromediators – are orders of magnitude lower (often nanomolar) than those of other endogenous electroactive species (see Table 1). Factors affecting determination of ECF concentrations are discussed elsewhere.[21]

Electroactive compounds in the ECF include: small, highly permeable, species such as dioxygen and NO; AA, that has a range of general antioxidant and specific neurochemical functions; neuromediator catecholamines such as DA and NE, as well as their metabolites DOPAC, 3MT and HVA; the 5-hydroxyindole neuromediator, 5HT, (serotonin) and its metabolite 5HIAA; amino acids and the purine metabolite UA. Electroinactive or badly behaved electroactive species, such as glutamate, glucose and lactate, can now be targeted in vivo using biosensors, especially enzyme-modified electrodes.[16,21]

The range of oxidation potentials for ECF analytes (against SCE) and estimated baseline extracellular concentrations are given in Table 1. In general, the higher the potential needed to detect the analyte of interest, the greater the risk of interference, so that at the potential needed to detect NO, say, interference by amino acids such as tyrosine and tryptophan, and molecules containing these moieties, needs to be considered. One feature that has helped separate voltammetric signals for AA and neuromediator metabolites from those of the neuromediators themselves is their ionic form at physiological pH. Because the former are anionic and the latter cationic at pH 7.4, modification of the electrode surface by anion repelling agents can increase the selectivity of the sensors for the parent neuromediator. The problems of VIV signal resolution have also been tackled with some success by choice of working electrode material, fine-tuning the shape of the applied potential, modification of the surface properties of the working electrode, and mathematical treatment of the recorded current.[21]

4 ELECTRODE TYPES AND PREPARATION

4.1 Auxiliary and Reference Electrodes

A wide variety of auxiliary and reference electrodes have been used for VIV. The main criterion is that the electrodes are small to minimize tissue damage upon implantation into the tissue, the most common placement site. Minimal disruption can also be achieved by locating these electrodes between the brain and skull (see section 6), although care is needed to ensure that these stay connected to a conducting medium. Using metal items already in place for other functions, such as a stainless steel guide cannula[4] or a supporting screw[62] as the auxiliary electrode, will also reduce damage. Recordings made in a metal frame or cage do not normally require explicit earthing of the animal, although this may be needed for recordings where plastic containers are used.

The reference electrode needs to be chosen with greater care because of the need for chemical reversibility at its surface. A common form is AgCl-coated Ag wire housed in a pulled micropipette containing a gelatinous solution of NaCl. This has the advantage that very small tip sizes are achievable, but disadvantages include the formation of bubbles in the tip and gradual leaching of the NaCl over extended periods in the tissue. In part to overcome these

two problems, the implantation of AgCl-coated Ag wire directly into the tissue is quite common. The consequent problem here appears to be the dissolution of the AgCl in the tissue, although a Nafion®-coating has been reported to extend the life of this type of implanted reference electrode.[75] Rather surprisingly, the most stable form of reference electrode for VIV is a bare Ag wire that can provide stable signals over weeks of recording;[76] the exact nature of the chemical reversibility is not clear, but may involve either Ag/Ag^+ or Ag/AgCl couples. Sample VIV data shown in sections 4.5 and 7.2 were recorded with this type of reference electrode.

The following description gives details of one approach to preparing auxiliary and reference electrodes for VIV, using Teflon®-coated silver wire (200-μm bare diameter). The Teflon® coating is removed from both ends to expose a 2–3 mm length of bare wire. An earth wire is also prepared using the same procedure. A gold connector is soldered to one end and the other end is gently manipulated, using a small tweezers, to produce a characteristic hook shape in the case of the auxiliary and earth. This enables them to be placed between the skull and dura (see section 6). The end of the reference is manipulated to produce a perpendicular kink about 1–2 mm from the end of the wire. This prevents the wire from penetrating beyond the cortical tissue. Once prepared, all electrodes (including the working electrodes) are inserted into a plastic socket via the gold pins (see section 6) and secured with dental acrylate. The design of various types of working electrodes for VIV is described below.

4.2 Platinum

Coated Pt wire normally forms the basis of Pt working electrodes used for VIV.[21] Either disk (100–300 μm diameter) or cylinder (~1 mm length) electrodes can be generated simply by removal of selected segments of the insulation, usually Teflon®. Diameters as low as 15 to 25 μm have been reported,[77,78] but in these cases additional mechanical support, usually a glass capillary, is required. To protect from fouling, Pt surfaces can be coated with a variety of membranes such as precast or cast cellulose acetate,[79] recast or electrodeposited perfluorosulfonated ionomers,[80] or electropolymerized films that can be as thin as 10 nm.[81,82]

4.3 Carbon Epoxy

A mixture of carbon paste (see section 4.5) and epoxy resin, force-filled into a glass capillary (~50–200 μm in diameter) and heat cured, provides a robust carbon epoxy electrode (CEE) for implantation in brain tissue. In the unmodified form, CEEs show little discrimination between AA, metabolites and neuromediators and early reports using CEEs with chronoamperometry for voltammetric detection of DA and 5HT in vivo may have been affected by changes in AA concentration.[83,84] Electrochemically pretreated, however, by the application of a potential high enough to electrolyze water, AA and catechol signals have been well-separated with pulse voltammetries, apparently by the cleaning,[85] roughening and oxidation of the electrode surface.[86] Anion-repelling polymer membranes (especially Nafion®) on the electrode surface that inhibit AA and metabolite access to the electrode[87,88] have also been used to improve the selectivity of CEEs for DA.[23] Although not widely used now for VIV, CEEs continue to be developed as forms of rigid carbon polymeric biocomposites.[89]

4.4 Carbon Fiber

Prepared by sealing single[90,91] or multiple[92,93] strands of carbon fiber into glass,[94] silica[95] or Teflon®[96] capillaries, carbon fiber electrodes (CFEs) are the most commonly used electrodes for VIV, principally because of their small diameter (5–50 μm) and easily varied length (0 to 500 μm). Sealing the fiber into the support is the most critical step in the preparation of CFEs and this has been achieved by a variety of methods, including the use of epoxy resin and, more recently, by the electrophoresis of paint.[55]

Armstrong-James and Millar[90] and Ponchon et al.[97] introduced CFEs in 1979, and their usefulness increased dramatically when it was demonstrated that resolution of AA (as peak 1) and catechol (as peak 2) could be achieved with pulse[61,98,99] and staircase[100] voltammetries following modification of the surface by application of either a triangular potential[91] or constant current[70,101] before use. Electrochemical and spectroscopic studies indicate that these treatments are likely to improve the performance of CFEs by increasing electron transfer rates[102–104] and adsorption of analyte[105,106] on the surface. Treatments have been explained in terms of a combination of electrode cleaning, increased area of active graphite edges from cracking, and oxidation of the surface.[104,107,108] It appears that the important parameter of the treatment is not the applied potential, but the current density passed, and the most reproducible results have been obtained under galvanostatic rather than potentiostatic conditions.[101,109] This factor may explain the difficulty some laboratories have experienced in producing good electrical treatment of CFEs, especially if the potentiostat used was not designed for the relatively high currents associated with this process.[110] Although electrochemical activation still remains the most common form of CFE treatment, laser,[102] heat[104,111] and chemical[112,113] treatments have also been successfully used. Other important factors shaping the effectiveness

of these modifications include the pH[114,115] and the buffer ions[102,116] of the treatment solution, phosphate buffer pH 7.4 being the most common medium.

Although electrical and other treatments of CFEs enable separation of AA and catechol signals, the problem of separating the two catechols (small DA and large DOPAC currents in DA-rich, NE-poor brain regions, such as dorsal striatum) is more difficult, but has been achieved using a number of different strategies. Nafion® coating of either treated or untreated fiber disks or cylinders repels AA and DOPAC, and allows both K^+-evoked[117,118] and electrically stimulated[119,120] DA release to be observed, although AA and DOPAC may interfere with the detection of slower drug-induced changes in DA.[74]

In addition to AA, DA and DOPAC detection, CFEs have also been used to monitor the 5-hydroxyindoles, 5HT and 5HIAA. By adjusting the electrical treatment parameters, the relative sensitivities and resolution of CFEs can be varied and a voltammetric peak (peak 3), containing contributions from 5HT, 5HIAA and UA, can be recorded in the ECF.[121–125] In acute experiments shortly after implantation of the CFE, the main contributors to peak 3 are 5HIAA (about 70%) and UA (about 30%) in both brain striatum[122] and spinal cord.[126] Peak 3 recorded 7 days following implantation, however, appears to be due entirely to 5HIAA.[127] See section 7.4 for further discussion of this phenomenon.

Figure 2 Staircase voltammogram (background subtracted) recorded at $5\,mV\,s^{-1}$ with a 160-μm diameter CPE in the striatum of a freely-moving rat several weeks after implantation. Peak 1 is essentially due to AA, peak 2 to 5HIAA, and peak 3 to the DA metabolite HVA. Increases in the extracellular concentration of catechols, DA and DOPAC, increase the current between peaks 1 and 2, considerably changing the potential of these peaks for large increases. Changes in the height, *h*, of peak 1, when there is no significant change in its peak potential, reflect variations in the concentration of AA in the ECF. When 320-μm diameter CPEs are used under the same conditions peak 2 is due to about 90% UA and 10% 5HIAA. Inset: Close-up of peaks 2 and 3 recorded with a 160-μm diameter CPE showing that, although these signals are of the order of 10^{-10} amps, they are measurable. Changes in the height of peak 3 can be used to monitor HVA in the ECF; a time course at 12-min intervals for this signal over a 3-day period is shown in Figure 4.

4.5 Carbon Paste

Carbon paste, prepared by thoroughly mixing carbon powder with either Nujol[4] or silicone oil[62] can be easily packed into cavities made by pulling the insulation over fine metal wires, producing disk electrodes of diameters as small as 160 μm, although diameters of about 300 μm have been generally used for VIV. A carbon/Nujol paste electrode with CV was used in one of the first reports of voltammetry in brain tissue with the aim of studying DA,[4] and a single peak was observed in rat striatum, attributed mainly to the oxidation of AA. Decreasing the scan rate to $10\,mV\,s^{-1}$ and semidifferentiation of the current later revealed three rather broad waves on the striatal voltammogram.[128] Further developments of the technique by the use of computer-controlled equipment,[129] silicone oil paste,[62] an additional reduction of the sweep rate to $5\,mV\,s^{-1}$, abandoning semidifferentiation, and subtraction of the background current recorded in situ, yielded CPE voltammograms consisting of three well-separated peaks in striatal tissue[130] (see Figure 2).

Peak-shaped signals are obtained by this non-differential method due to both thin-layer behavior in the compartment around the implanted electrode[66,131,132] and adsorption of the analytes.[65,133] Because of the lack of clear resolution between AA and catechols by CPEs, a wide variety of techniques have been used to characterize the CPE signals recorded in rat striatum in vivo: theoretical analysis;[132] electrochemical studies in vitro;[62,129] microinfusion of candidate substances[129,134] and metabolizing enzymes[133,135–137] beside electrodes implanted in brain tissue; lesions to striatal afferent pathways;[71,135,138] pharmacological perturbations using drugs with well-characterized actions;[71,134,136,139] and comparison with other in vivo techniques, such as microdialysis.[133,140]

These experiments, reviewed recently,[64] indicate that peak 1 (see Figure 2) is due mainly to AA; moreover changes in the height of peak 1 result from variations in the extracellular concentration of AA, provided there is no significant shift in the relative potentials of peaks 1 and 2. When such potential shifts occur they are not due to electrocatalysis but to the algebraic combination of the AA peak (at the normal potential of peak 1) and the

catechol peak some 60 mV higher, and difference voltammograms can be used to analyze the changes in terms of fluctuations in the catechol concentration.[129] Under most circumstances (some exceptions being stroke[141] and death[142,143]) these latter changes are mainly due to DOPAC, because the level of DA in striatal ECF has been estimated by a range of techniques to be less than 50 nM.[72,144,145] The main component of peak 2 is UA with a minor contribution from 5HIAA when ~300 μm CPEs are used,[133] whereas peak 2 recorded with 160 μm CPEs is due to 5HIAA almost exclusively.[139] Changes in the height of peak 3 are directly proportional to changes in the extracellular concentration of methylated metabolites of DA. Normally this is HVA,[71] but when MAO is inhibited pharmacologically, 3MT may contribute[140] (see Figure 1).

The main advantage of CPEs is their stability over several months of recording in vivo.[8] It appears that lipids present in the tissue remove pasting oil from the surface[19] and reverse poisoning caused by proteins.[70] This factor may also undermine the use of CPEs that have been chemically modified with lipophiles, such as stearic acid, for the detection of DA[146,147] because such species can be removed from the electrode surface following contact with brain tissue,[148] although this point is still a subject for debate.[17] The principal disadvantage of CPEs is their comparative large size, and neurochemical studies have been limited to relatively large brain regions such as striatum,[149–151] nucleus accumbens,[151–153] cortex,[154,155] pallidum[156] and hippocampus.[151,155,157] None of these brain areas can be considered an homogeneous array of cells – even the striatum consists of an array of substructures[158] – and so the development of an electrode with the dimensions and sensitivity of CFEs and the stability of CPEs is an on-going objective for VIV.

4.6 Biosensors

A biosensor can be defined as a device that involves the immobilization of a sensitive and selective biological element on, or within close proximity of, an analytical detector. The range of biological components that have been used in the development of biosensors is extensive; typical examples include enzymes, plant and animal tissues, microbes and antibodies. The type of analytical detector employed is also wide ranging (e.g. electrodes, optical fibers and crystals) and is generally used to classify the biosensor. The fundamental principles, designs and wide ranging applications of biosensors have been described in detail in comprehensive reviews in the literature.[16,159,160]

The primary reason for developing biosensors for applications in vivo is the ability to measure biologically important compounds that are either electroinactive or only poorly electroactive at analytically useful potentials. Such compounds include glucose, lactate and glutamate (see Table 1). Enzyme-modified electrodes, particularly amperometric devices, are the most thoroughly investigated sensors in the biosensor field. Their origin dates back to the first reported biosensor (for glucose) by Clark and Lyons in 1962.[161] Prolific research on the development and applications of enzyme-modified electrodes over the intervening three decades has yielded sensors for a large variety of analytes, including glucose, ethanol, cholesterol, bile acids, choline, purines and amino acids.[159,160] However, despite the significant advantage of continuous real-time monitoring afforded by these electrochemical devices, only a small percentage have actually been used in vivo for chemical analysis in the living brain. This is primarily due to the many difficulties associated with performing direct measurements in such complex environment as brain ECF (see section 2.2). Important considerations include the immunological response to the implanted sensor, the presence of electrode poisons and endogenous interferences, restriction of mass-transport by brain tissue, effects of depletion, and the availability of suitable enzymes for the specific analytes of interest. The sensors that have been successfully used for VIV have all been amperometric flavoprotein oxidase-modified electrodes for either glucose, lactate, glutamate or choline.[21]

The immobilization of the enzyme component onto the electrode surface has been achieved using various strategies. The most common methods include: direct physical adsorption; covalent bonding (e.g. via carbodiimide) and/or cross-linking (e.g. via glutaraldehyde); entrapment behind pre-cast (e.g. cellulose acetate), cast (e.g. polyurethane), and electrodeposited (e.g. Nafion®) membranes; and more recently, entrapment within electrosynthesized polymeric matrices (e.g. polypyrrole and polyphenylenediamine).[16,159,160]

The classic and most common enzyme-modified electrode is the glucose biosensor incorporating the oxidoreductase enzyme, glucose oxidase (GOx, isolated from *Aspergillus niger*, E.C. 1.1.3.4). This type of sensor has become the model system primarily due to the importance of glucose monitoring in the disease diabetes mellitus, and the fact that glucose determination in various body fluids, such as blood, plasma and urine, remains one of the most common analyses performed in clinical laboratories. Additionally, GOx has good substrate specificity, a high turnover rate, and excellent stability that makes it ideally suited for use in a biosensor.[162] GOx is a flavin-containing enzyme that catalyses the oxidation of D-glucose in the presence of oxygen, producing hydrogen peroxide:

$$\beta\text{-D-glucose} + \text{GOx/FAD} \longrightarrow \text{D-glucono-}\delta\text{-lactone} + \text{GOx/FADH}_2$$

$$\text{GOx/FADH}_2 + \text{O}_2 \longrightarrow \text{GOx/FAD} + \text{H}_2\text{O}_2$$

where FAD is the oxidized form of the prosthetic group, flavin adenine dinucleotide. The development of amperometric enzyme electrodes has focused on the measurement of the glucose signal generated by the reaction of the reduced enzyme ($GOx/FADH_2$), and can be categorized broadly in terms of first, second and third generation devices.

Classic or 'first generation' enzyme-modified electrodes involved monitoring either the consumption of oxygen,[163] or the formation of hydrogen peroxide.[164] These devices suffered from a number of drawbacks including fluctuations in response due to low and/or variable oxygen tension, and interference from endogenous electroactive species due to the large applied overpotential (typically +700 mV versus SCE) required for hydrogen peroxide oxidation. Despite this, hydrogen peroxide detecting sensors still remain the most common type of enzyme-modified electrode, and over the years a number of attempts have been made to overcome these problems. In particular, nonphysiological electron transfer mediators, immobilized on the electrode surface or within the enzyme layer, have been used to replace oxygen, the natural or physiological enzyme mediator. Such artificial mediators must exhibit several important characteristics: reversible electron transfer kinetics at the electrode surface, and rapid homogeneous kinetics for the enzymatic reaction in solution; possess a low overpotential for regeneration of the oxidized form of the mediator; and be stable in both oxidized and reduced forms. Many such redox mediators have been investigated and found to meet these criteria. Typical examples include ferrocinium ions, quinones, ferrocyanide, ruthenium compounds and tetrathiafulvalene.[21] However, although these 'second generation' devices have the advantage of a low operating potential, and elimination of oxygen from the reaction scheme, they do suffer from a number of problems. These include leaching of mediator from the electrode surface or enzyme layer,[165] toxicity in biological tissues,[166] and electrochemical interference, e.g. oxidized ferrocenes can be reduced by AA.[162] Additionally, the complete insensitivity to oxygen tension sometimes claimed for this type of sensor has been questioned for certain mediators.[167] More recently, another form of mediated system that has found widespread usage is that of entrapping the enzyme in a redox polymer (e.g. poly(ethylene glycol) diglycidyl ether) that can serve as both the mediator and enzyme immobilization matrix.[168,169]

Eliminating the mediator from the reaction scheme and achieving the simplest approach of direct electron transfer from the reduced enzyme to an electrode has proved extremely difficult. This is generally accepted to be because the distance between the FAD active site and the electrode is such that direct electron transfer to the electrode takes place slowly or not at all. Consequently, very few mediatorless or 'third generation' enzyme electrodes have as yet been devised. The first report of such a device was by Albery et al.[170] using one-dimensional organic conducting salt electrodes, e.g. tetrathiafulvalenium tetracyanoquinodimethanide (TTF^+TCNQ^-), to eliminate the mediator from the reaction scheme. However, the mechanism of electron transfer at these organic salt electrodes is now generally accepted as being a mediated process involving species such as $TCNQ^0$.[171] Since then, successful direct electrical communication between GOx and an electrode surface has been claimed by several groups using a variety of techniques. These include direct electron transfer between covalently bound GOx and a cyanuric chloride modified graphite electrode,[172] between GOx immobilized on glassy carbon modified by aminophenylboronic acid,[173] and between GOx immobilized via adsorption and a variety of cross-linking reagents onto platinized carbon paper electrodes.[174] Urea has been used to modify the enzyme structure by opening the active site, thus making it more accessible to a ferrocyl acetamide-modified electrode, composed of arrays of electron-transfer relays.[175] This type of chemical modification of the enzyme has led to the development of 'electrically wired' enzymes.[176] A hydrophobic interaction between GOx and TTF^0 molecules has also been reported with the resultant opening of a direct path of electrical communication between a Pt electrode and the flavin redox center.[177]

Finally, before a biosensor can be used reliably in vivo it is necessary to perform a detailed characterization in vitro of the device. Such a characterization typically includes studies of sensitivity, linear calibration range, response time, interference properties, and stability.[178,179] However, it is also very important that a detailed in-vivo characterization be performed in the target environment before the sensor is used in direct physiological investigations.[180] This is to ensure that the properties obtained in the artificial in-vitro environment are maintained in the more complex living biological milieu.

5 VOLTAMMETRIC TECHNIQUES USED IN VIVO

In VIV one is usually interested in how the concentration of a particular neurochemical is changing with time

on a scale from milliseconds to days. The choice of technique will therefore be restricted by the time resolution needed, in addition to other factors such as how well the working electrode can discriminate between the different electroactive species present in the ECF. Since the vast majority of substances of interest in VIV studies undergo oxidation, rather than reduction reactions, the descriptions that follow will be for oxidative voltammetry. The forms of voltammetry most often used for neurochemical analysis in vivo have been reviewed.[8–22]

Different forms of voltammetry can be categorized on the basis of the time resolution achieved for detecting changes in the concentration of species in the ECF. Fast techniques with resolutions of the order of seconds or less are chronoamperometry, fast cyclic voltammetry (FCV), differential pulse amperometry (DPA) and constant potential amperometry (CPA), and these methods are generally used to detect stimulated changes in neuromediator overflow. Slow techniques with time resolutions of the order of several minutes are linear sweep voltammetry (LSV), staircase voltammetry (SCV), differential pulse voltammetry (DPV) and differential normal pulse voltammetry (DNPV) at low scan rates.[13,21] The latter are usually used in studies of neuromediator metabolites as well as AA and UA. The minimum interval between scans is limited not only by the sweep time but also by the time taken for the concentration of the electrolyzed species in the compartment around the implanted electrode tip to return to its unperturbed value by means of tortuous diffusion through the tissue matrix (see Figure 2).[69]

5.1 Chronoamperometry

This is one of the simplest forms used for VIV and was one of the first.[83] Initially, the potential is held at a sufficiently low level where no oxidation occurs. A square pulse is then applied for between typically 100 ms and 1 s to a value corresponding to a high overpotential for the particular analyte of interest, and the current sampled close to the end of the pulse (usually integrated over a short time interval) where the ratio of faradaic to charging current is large. Because the initial currents associated with chronoamperometry are among the largest produced by VIV, it is interesting to note that simultaneous recording of nerve cell firing during this,[181] and other relatively high current forms of VIV,[182,183] indicate that voltammetry in nervous tissue does not appreciably interfere with the normal electrical properties of neurons.

Although chronoamperometry has an advantage for VIV of good temporal resolution (up to 200 ms[184]), a major limitation in its simplest form is the inability to differentiate between compounds with similar oxidation potentials. Thus, because AA tends to oxidize at least to some extent at lower potentials than monoamine neuromediators at unmodified electrodes, early in-vivo chronoamperometric data may have been contaminated with contributions from AA. Two later innovations have revived interest in chronoamperometry: the use of anion-repelling polymer membranes (especially Nafion®) on the electrode surface that inhibit AA and metabolite access to the electrode; and the development of reverse-pulse chronoamperometry that allows discrimination between different species oxidized based on the ratio of their oxidation/reduction response.[21,24,185–187]

5.2 Linear Ramps

The general feature of this group of voltammetric techniques is the application of an essentially linearly increasing potential from an initial value where no oxidation occurs to a final value at a fixed scan rate (5 to 100 $mV\,s^{-1}$ for VIV), allowing the sequential oxidation of a range of analytes. The simplest example is LSV where a truly linear (from an analog device) potential is used. Because many VIV studies now use computer-controlled digital equipment,[72,100,129] the potential is incremented in discrete steps so that SCV is obtained. In studies with CFEs, where relatively large steps are involved (10 mV), a differential form of analysis is used where the current measured on a given step is subtracted from the next value to give a peak-shaped voltammogram with cylindrical microelectrodes.[100,188]

If the potential is scanned back to the initial value after reaching the maximum point, the technique is CV. This approach is used very rarely at slow scan rates for VIV because most of the oxidation reactions are chemically irreversible in vivo.[4] However, FCV at sweeps of about 300 $V\,s^{-1}$, where the oxidized form is reduced before the following chemical reaction can occur appreciably, is now widely used for VIV because the different components in the ECF can be distinguished on the basis of the shape of their oxidation–reduction currents.[18,22,120,189–195]

The main advantage of the slow ramp techniques is that a number of separate signals associated with different neurochemicals of interest can be obtained in the same voltammogram using either CPEs (see Figure 2) or CFEs.[21] A consequent disadvantage is the time taken to sweep the potential (up to 2 min at 5 $mV\,s^{-1}$) as this restricts the time resolution of the concentration determination to a minimum of about 5 min for 5 $mV\,s^{-1}$[157] and 2 min for 100 $mV\,s^{-1}$[100] to allow for the slow recovery of ECF levels of analytes electrolysed from the compartment around the electrode tip. For FCV the situation is reversed because a good time resolution of 100 ms has been achieved,[196] but only

a single substance can be detected under the conditions of any given experiment.

5.3 Pulsed Techniques

There is a wide variety of pulsed voltammetric techniques available:[13,21] DPV, where a pulse of fixed amplitude is superimposed on a linearly increasing ramp, and the current, sampled just before the pulse, is subtracted from that measured close to the end of the pulse; normal pulse voltammetry (NPV) in which a pulse of increasing magnitude is applied relative to a constant resting baseline potential, and the current sampled near the end of the pulse; DNPV, where a double pulse of fixed potential difference is applied with increasing amplitude from a constant baseline; and DPA, where a double pulse of fixed potential difference is applied at fixed amplitude and the difference in current at the two pulses plotted as a function of time.

The first pulsed voltammetric form for VIV with carbon electrodes was NPV.[97] DPV, however, has been widely used, although DNPV is also common and DPA has been used more frequently in recent reports.[197–199] The main advantage of the pulse approach is that the different parameters of the potential form – pulse amplitude, duration and separation – can be adjusted to provide maximum resolution of the target analyte based on differences in its kinetic and adsorption properties on the electrode.[99,200] In addition, capacitance currents can be minimized if the subtraction is carried out before the amplification stage. Square wave voltammetry that involves sequential measurement of oxidation and reduction currents[201] has not been used widely in VIV, but has an advantage that good peak resolution can be achieved at relatively fast scan rates of about $125\,mV\,s^{-1}$[202] compared with about $10\,mV\,s^{-1}$ for DPV and DNPV.

More recently, differential multipulse amperometry (DMPA) has been developed and applied to neurochemical studies.[21,203] Here potentials determined using DNPV are used to construct a voltage profile consisting of four short pulses (two pairs) repeated indefinitely. The pulse potentials were chosen so that the difference in amperometric response between the first two pulses was due to DA, whereas 5HT was detectable using the second pair. Sub-second detection of these two neuromediators appears possible using this approach, although the data available to date is limited.

5.4 Constant Potential Amperometry

In CPA, the current is monitored essentially continuously at a fixed potential where the redox reaction of the analyte of interest occurs, usually under diffusion-limiting conditions. This form has recently been used for VIV because of its high time resolution, but applications are limited to situations where the oxidation of only one analyte can be assumed with some certainty as in the detection of AA at low potentials,[137,151,204] and catecholamines following stimulation of specific pathways in vivo[22,205–207] and from isolated cells in vitro.[22,47,50,55,94] The specificity of biosensors makes them ideal devices for use with CPA, and this will be discussed separately below.

6 SURGICAL PROTOCOL FOR VOLTAMMETRY IN VIVO EXPERIMENTS

6.1 General Considerations

Before carrying out any surgical procedure it is important to think carefully about the facilities that are available and whether they are adequate for what is to be achieved. Implantation of microelectrodes for VIV requires good aseptic conditions with proper sterilization of equipment and instruments. Surgical procedures should be as atraumatic as possible. It is important to learn how to handle surgical instruments correctly and to avoid damaging tissues by grasping them with excessive force or with inappropriate instruments. Surgery on small animals such as rodents should be performed in a designated surgery room. A recovery area should be provided where animals can be taken after surgery for postoperative care and observation while recovering from the procedures and anesthetic.

Male Sprague–Dawley rats weighing between 200 and 300 g (mature young adults) are generally used in VIV experiments. The animals are usually housed in a temperature-, humidity- and light-controlled environment, with free access to food and water. Sample protocols for VIV experiments are described in the following sections.

6.2 Anesthesia

Successful anesthesia does not depend simply on the types of drugs, doses, and routes of administration used. A good standard of animal care must also be maintained, both pre- and postoperatively, including reduction in stress and provision of pain control. All these factors must be taken into account when designing an anesthetic regime. A typical regime used to induce anesthesia for implanting microelectrodes is as follows.[208] A combination of the opiate analgesic fentanyl ($0.32\,mg\,mL^{-1}$)/fluanisone (Hypnorm, $0.1\,mg\,mL^{-1}$) and the benzodiazepine midazolam (Hypnovel, $5\,mg\,mL^{-1}$), mixed 1 : 1 : 2 with sterile water, is injected intraperitoneally (i.p.) at a volume of

3.3 mL kg^{-1}. This results in surgical anesthesia within 4–5 min, that is maintained for the 45 min of the surgical procedure. Both corneal and hind limb withdrawal reflexes are tested to confirm the level of surgical anesthesia. In order to complete the cementing process at the end of surgery (see section 6.3) 1–3 mg kg^{-1} of midazolam is administered intramuscularly. On completion of the surgery and cementing, an injection of naloxone (0.1 mg kg^{-1}, i.p.) is given to reverse the opiate effect and prevent respiratory depression. Post-operative analgesia is provided in the form of a single injection (0.1 mg kg^{-1}, subcutaneously) of Vetergesic (buprenorphine) given immediately following the surgery.

6.3 Surgery and Recovery

Once surgical anesthesia is established, the animal is placed in a stereotaxic frame. Body temperature is maintained at 37 °C throughout surgery with an isothermal heating pad. A midline incision 1–2 cm in length is made to reveal characteristic skull markings, bregma and lambda, which are used as coordinate reference points. The underlying muscle and fascia are scraped away and the skull levelled between bregma and lambda. A schematic of a typical surgical and implanting process is shown in Figure 3(b). Artery clamps are used to hold the incision open. With the aid of a dissecting microscope, small burr holes are made in the skull to enable implantation of small support screws and the recording electrodes. The latter are positioned in the target brain area according to coordinates obtained from a stereotaxic atlas.[209] For example, for rat striatum (left and right) that is the most widely studied region for VIV, the coordinates are: anterior/posterior, +1.0 mm from bregma; mediolateral, ±2.5 mm from bregma; and dorsoventral, −5.0 mm from the dura. The reference electrode (8T Ag wire, 200-μm bare diameter) is placed in the cortex, the auxiliary electrode (8T Ag wire) between the skull and dura, and an earth wire (8T Ag wire, applicable with plastic animal bowls) attached to one

Figure 3 (a) Schematic representation of the electrode assembly suitable for VIV. A gold connector is soldered to one end of each electrode. Each electrode is inserted into a six-pin Teflon® socket via the gold pins. This socket, which is secured to the skull with dental acrylate after implantation, can then be connected through a flexible screened six-core cable, mounted through a swivel (allowing free movement) above the animal's head, to the electrochemical instrumentation. The design of the various types of electrodes is described in section 4. (b) Schematic representation of a surgical and implanting process: (i) A midline incision 1–2 cm in length is made over bregma (cross) and the underlying muscle and fascia scraped away. Artery clamps are used to hold the incision open. Small burr holes are made in the skull to enable implantation of support screws and the recording electrodes. (ii) Positioning of the reference electrode (200-μm bare Ag wire) in the cortex. (iii) Positioning of the auxiliary electrode or earth wire (200-μm bare Ag wire) between the skull and dura. The auxiliary may also be simply attached to one of the support screws.

of the support screws. All electrodes are secured with dental acrylate. The clamps are removed and a second application of acrylate serves to close the incision and to further stabilize the electrodes.

Once the dental acrylate has sufficiently hardened the animal is removed from the stereotaxic frame and returned to its home cage to recover, with its body temperature controlled while the analgesic effect of the opiate persists. At the end of this period, if signs of pain are observed, an additional injection of buprenorphine is given subcutaneously. The animal room is normally maintained on a 12/12 hour light/dark cycle.

6.4 Assessment of Animal Health

All animals should be monitored routinely following surgery for any signs of pain or distress. During the recovery period food and water should be freely available. A post-operative record should be kept that includes information on urine, faeces, food and water intake, drugs administered, and stress scoring. This practice ensures that only healthy, pain free animals become experimental subjects. Generally, a post-surgery period of 24 h is necessary and sufficient for recovery.

6.5 Experimental Conditions

There are two main categories of experimental conditions for VIV. The first, in terms of technical simplicity, is when recording takes place while the animal is still in the stereotaxic frame under the influence of anesthetic; this is termed an 'acute' preparation. The following factors must be taken into account when analysing data recorded under these conditions: concentrations of analytes may be effected by acute tissue damage; the BBB may not be intact; and the effects of the specific anesthetic agents on the concentration of target analytes.[21]

The second, and now more common, 'chronic' preparation involves allowing the animal to recover from anesthesia (see section 6.3). Implanted electrodes can be connected to the recording equipment through, for example, a six-pin Teflon® socket (see Figure 3a), and a flexible screened six core cable, that is mounted through a swivel above the rat's head. This arrangement allows relatively free movement of the animal. Possible complications with this preparation include gliotic reaction by the tissue and perturbations of the chemical environment around the implanted electrodes (see section 7.4).

6.6 Hazard Assessment

As with all procedures in a laboratory, it is now considered wise to undertake and document a safety hazard assessment of the materials and actions involved before carrying out the procedure, in which the hazards are identified, the risks assessed and control measures put in place to minimise the risks. Particular hazards for VIV experiments include: being bitten and contracting disease; developing allergic reactions in the respiratory system and skin; and being injured by scalpels and needles. Control measures associated with these hazards should include the careful handling of animals, appropriate inoculation of personnel, the wearing of face masks and gloves, and the careful use and disposal of sharps.

7 DETECTION OF SUBSTANCES IN BRAIN EXTRACELLULAR FLUID

The brain operates at a range of levels – molecular, cellular, regional and as a whole – and the choice of voltammetric technique depends to a large extent on what one wants to study. Microdialysis has also been developed to sample the ECF for neuroactive species, usually followed by separation with high-performance liquid chromatography (HPLC), and either electrochemical or spectroscopic detection (see section 8). An advantage of microdialysis is the wide range of compounds: neuromediators, metabolites, amino acids, drugs, etc. that can be collected in each sample and separated reliably using recent advances in HPLC technology.[210] The main disadvantages of dialysis are the relatively large probe size available (minimum $\sim 200\,\mu m$) and the poor time resolution, ranging from 2–10 min, although about 1 min has been achieved recently with capillary electrophoretic separation.[211] Although voltammetry has been limited until recently to electroactive analytes (a limitation that is being overcome with the development of enzyme-modified electrodes; see section 4.6), its advantages of small probe size and high temporal resolution, which have been achieved in many studies, allow investigations not possible with microdialysis.

The vast majority of neurochemical studies employing voltammetry have been carried out using rats, although there are examples of other species being investigated, such as snails,[212] turtles,[213] mice,[214] hamsters,[92] guinea-pigs,[215] cats,[207] sheep[216] and non-human primates.[217]

7.1 Electroactive Neuromediators

Although brain slices offer a convenient and effective way of manipulating individual neuronal pathways to study their pharmacology and physiology, the function and response of a given projection in vivo depends to a large extent on the myriad of connections to and from other pathways, many of which are severed in the slice.

Voltammetry has therefore been used in vivo to investigate neuromediator function in the context of the living brain, and in many cases its relationship to behavior.[21] However, because the baseline extracellular concentrations of electroactive monoamine neuromediators are of the order of nanomolar[72,144,145,218,219] (Table 1) due to efficient reuptake mechanisms[218] (Figure 1), many of the techniques available are not sensitive enough to detect these levels. A number of approaches have been used, therefore, to monitor artificially high levels of neuromediator overflow in the ECF, mainly in acute, anesthetized preparations.

High doses of the MAO inhibitor, pargyline, greatly reduce DOPAC levels in the ECF (see Figure 1) so that peak 2 recorded with CFEs and DPV is abolished.[61] The introduction of DNPV,[200] which shows a higher sensitivity for DA, revealed a small DA signal close to the potential of peak 2 in pargyline-treated rat striatum, and later the development of DPA[99] allowed the detection of DA with high time resolution in a number of brain regions under similar conditions.[214,220,221] In other approaches, chronoamperometry, FCV or CPA with CFEs has been used to monitor stimulated DA[22,195,222,223] and NE[7,205,224] release in a number of brain areas.[21] A successful model based on release and uptake parameters[225] has been used to understand the relationship between release and stimulation frequency for the dopaminergic nigrostriatal pathway, and how the effectiveness of drugs used clinically, including neuroleptics, can depend on firing rate.[144,226] In contrast, baseline (non-stimulated) ECF levels have been measured for DA as low as 2 nM in striatum,[219] and for 5HT[227] in frontal cortex (5 nM) and raphe nuclei (10 nM) using Nafion®-coated electrochemically-treated CFEs with DPV, and an important study with these electrodes has shown that extracellular concentrations of 5HT and 5HIAA are not necessarily correlated.[228] Although promising, these electrodes have not found widespread use for VIV, presumably due to reproducibility and stability problems.

Until recently, these approaches had a limitation that anesthesia was involved during the VIV recordings. A range of general anesthetics are known to affect the firing rate and responsiveness of neurons and the release, uptake and metabolism of a variety of neuromediator substances. This is not surprising because the widely distributed γ-aminobutyric acid (GABA)-receptor/chloride-channel complex may be a common mediator in some aspects of anesthetic action.[229] Indeed, specific examples of different (sometimes opposite) VIV results in the presence and absence of anesthetics have been reported.[149,157,230] The finding, therefore, that basal concentrations of DA and 5HT can be detected with mathematical deconvolution[231] of the DNPV signals recorded with electrochemically treated CFEs in unanesthetized, freely moving rats is an important advance in VIV.[21] More recently, replaceable electrode systems and other strategies have been applied to monitor behaviorally-related changes in the concentration of monoamine neuromediators with CFEs, including sexual behavior,[232] free-choice novelty,[233] and electrical self-stimulation of brain reward centers.[195]

7.2 Electroactive Neuromediator Metabolites

A principal aim of VIV is the generation of a signal as closely related as possible to neuromediator release in the synapse. An important question that has yet to be resolved is which species in the ECF is the closest reflection of synaptic release. The main candidate is the neuromediator itself overflowing into the ECF (see Figure 1). However, there are populations of neuromediator receptors outside the synapse and transmitter in the ECF may have a different function to that in the synapse. Moreover, there appear to be cases where environmental stimulation (e.g. presentation of food after a fast) causes activation of nigro-striatal DA cells without associated increases in striatal ECF DA levels.[234] The link between extracellular metabolite levels and release rate is also problematic. In the case of the monoaminergic systems, DOPAC and 5HIAA are more likely to reflect synthesis rate than release (see Figure 1). However, COMT (one of the enzymes required for HVA production) is located outside the nerve terminal[235] (see Figure 1). It has been suggested, therefore, that HVA may be a better index of DA release than DOPAC, and that HVA is a fair index in the absence of drugs, at least on a timescale of minutes.[13]

A principal advantage of some metabolite signals is that they are stable over several days of recording with the same electrode, and therefore allow investigation of the relationships between neurochemical events and observed behavior over extended periods.[76] A disadvantage is that changes in metabolite concentrations are much more sluggish than that of the corresponding neuromediator with lags of up to 30 min in the peak responses.[236] The main VIV techniques used to monitor neuromediator metabolite levels in the ECF are CFEs with either SCV, DPV or DNPV (DOPAC as peak 2 and 5HIAA as peak 3) and CPEs with SCV (HVA as peak 3; see Figure 2). The CFE 5HIAA signal has been used to detect 5HT metabolism in the suprachiasmatic nuclei, raphe nuclei and hypothalamus over the sleep/wake cycle, and as a result of stress.[21]

Diurnal variations in DA metabolism using the CPE HVA signal have been recorded in frontal cortex, nucleus accumbens and striatum and correlated with simultaneously monitored motor activity (Figure 4). Rats are nocturnal and show a high level of locomotion during the dark period. Electrochemical detection of HVA

Figure 4 Time course over 3 days of changes in the methylated DA metabolite signal (peak 3, see Figure 2) recorded with a CPE in the striatum of a freely-moving rat at 12-min intervals (a) and simultaneously monitored motor activity (b). Each day's recording started at 12.00 h, with lights off from 20.00 h to 08.00 h. The period shown corresponds to days 3 to 6 of a longer recording period, and demonstrates the stability of CPEs in brain tissue. Similar data have been used to compare the activity of DA terminals in different brain regions during motor behavior, and to test observed correlations between these two parameters with physiological and pharmacological perturbations.

shows that, associated with this high activity phase, DA transmission in certain forebrain areas is also elevated. Correlation analysis indicates that DA transmission in the latter two brain structures, but not in frontal cortex, is closely involved in motor behavior.[154] This correlation can be disrupted for striatal, but not accumbens, HVA by valium-type anxiolytic drugs such as the benzodiazepine, flurazepam.[237] Changes in HVA associated with trained lever-pressing behavior have also been reported for striatum and nucleus accumbens.[238]

7.3 Ascorbic Acid

With its high concentration and ease of oxidation, AA is probably the simplest molecule to detect and monitor in brain ECF using VIV techniques. Microdialysis methodologies, however, are not as fortunate in that they appear to have difficulty recovering and detecting changes in brain AA. This may be due to the presence in brain tissue of non-dialysable dehydroascorbate reductase that normally protects AA from oxidation in the ECF,[239] and to the oxidation of AA in the buffer, catalysed by trace amounts of heavy metal ion impurities.[240] These factors, together with the continuous depletion of ECF AA caused by perfusion, and the difficulty in separating AA successfully from the solvent front at the HPLC stage, may explain such analytical difficulties.[63]

Voltammetric AA signals have revealed that the extracellular concentration of AA in discrete brain areas of awake animals changes with the animal's behavior

and responds to the administration of drugs. On the basis of experiments in vitro with synaptosomes, a model relating AA in the ECF with the uptake of excitatory amino acids through a heteroexchange mechanism has been proposed to explain these variations.[241] The in vivo applicability of the model has been tested by a number of independent laboratories using a variety of lesion, stimulation, microinfusion and other pharmacological experiments, and so far has not been invalidated.[63,157,242–245] It remains to be seen, however, whether this idea will survive more detailed testing in vivo, and whether AA will prove a useful tool for investigating in vivo the functions of glutamate, a ubiquitous neurotransmitter in the CNS.

7.4 Uric Acid

The origin and significance of changes in brain extracellular UA levels are not clearly understood, not least because the concentration of UA in the ECF depends to a great extent on the experimental conditions.[246] Until recently it was believed that xanthine oxidase, the enzyme involved in the metabolism of hypoxanthine to UA, was not present in brain tissue and thus there have been few reports on the production and significance of this purine metabolite in the CNS. There is now, however, direct evidence that UA is produced in the mammalian brain. Furthermore, the use of in vivo monitoring techniques has shown that, in addition to spontaneous diurnal variations, a number of different stimuli give rise to changes in the extracellular concentration of brain UA, including: electroconvulsive shock; ischemia; systemic and intracerebral administration of drugs; feeding and drinking behavior; and motivated lever pressing.[246] It appears, however, that the concentration of UA in brain ECF depends markedly on the size of the probe used and on the length of time the probe is in contact with the tissue.[139]

Thus, a possible explanation has emerged for the apparently paradoxical results for UA and 5HIAA obtained with CPEs and CFEs. For several hours after an electrode is implanted the concentration of 5HIAA and urate are similar in the low micromolar range. However, the vast majority of CPE data have been recorded in awake freely-moving animals several days following implantation. With large CPEs (320-μm diameter), the concentration of UA increases to about 50 μM by 24 h after surgery and remains high for months; peak 2 is much larger compared with the acute condition and reflects mostly (about 90%) UA.[133] When chronically implanted small electrodes are used such as CFEs or 160-μm diameter CPEs, the low level of UA observed under acute conditions actually decreases to below the limit of detection (about 1 μM[127,139]). This phenomenon appears to be linked to the lesser extent of glial reaction to the smaller electrodes, and suggests that the low micromolar level of UA detected in the ECF under acute conditions may arise from leakage across the damaged BBB.[246]

It is unclear whether extracellular UA reflects glucose utilization or neuromediator adenosine metabolism, although the weight of evidence to date favors the latter.[246] Changes in the concentration of UA detected in the ECF under acute conditions (including studies using removable electrodes and dialysis cannulae in awake animals) may reflect variations in blood flow, because the BBB is damaged temporarily and blood contains relatively high UA levels. For chronically implanted large probes (>160-μm diameter), tissue reaction results in the extracellular concentration of UA being significantly higher than normal. One import of these data is that tissue perturbation caused by the implant is highlighted, as is the need to continue to develop small stable in vivo probes.

7.5 Dioxygen

Molecular oxygen was one of the first substances detected voltammetrically in vivo, both in brain[59,60] and peripheral tissues,[247] using noble metal and carbon electrodes that continue to be the electrode materials of choice for this analyte.[180,248–250] The spread of mean concentrations reported for oxygen in cerebral tissue is quite tight, ranging from 40 μM,[251] through 50 μM[252] and 60 μM,[253] to 80 μM.[254,255] The anatomical distribution of concentrations reported within the brain is wide, however, depending on the depth of penetration of the sensor into the tissue[256] and the heterogeneity of the tissue.[251,257] Brain tissue oxygen responds to a range of perturbations including electrical stimulation[254] and neuromediator release,[258] with more rapid turnover in cerebral cortex compared with other brain areas.[252] There is good evidence that oxygen levels in brain ECF are positively and strongly correlated with cerebral blood flow,[198,259,260] and it is now possible to monitor continuous brain tissue oxygen, carbon dioxide, pH, and temperature with simultaneous recording in the blood, using multisensor probes.[261]

7.6 Nitric Oxide

NO is a relatively recently recognized neuromediator responsible for a variety of physiological responses,[262–264] and initial attempts at its electrochemical detection in biological tissues have been reviewed.[262,265–267] One of difficulties associated with detecting this free radical is its short half-life (<1 min) in tissues containing oxygen, and informal feedback from users of NO sensors (including commercial ones) suggests dissatisfaction with their

performance. Although NO can be reduced at about −900 mV versus SCE with a gas membrane-covered Pt electrode,[265] interference by molecular oxygen at this potential means that reduction mode is not suitable for NO detection in vivo. Monitoring is therefore normally carried out at high anodic potentials. A range of electrode materials have been employed at between 0.6 and 1 V, including Pt,[268] glassy carbon[269] and CFEs,[270–272] with metalloporphyrins being used in many cases to electrocatalyze the oxidation (~300 mV lower than at bare electrodes), and polymers such as Nafion® to block interference by anionic nitrogen oxides and other anions. The concept of tissue concentration of such a reactive species is questionable, but estimates lie in the range of 10–100 nM[268,273] for brain ECF, emphasizing the need for high sensitivity and selectivity for NO sensors used for VIV. The need for high potentials to detect NO at the low levels present in tissue, even when electrocatalysis is exploited, makes it difficult to avoid interference from a range of species, including AA, UA, and electroactive amino acids such as tyrosine and tryptophan, so that caution is needed in interpreting VIV data for NO. Despite these limitations, brain NO detection in vivo continues to be seen as an important objective, and reports of monitoring NO across sleep/wake cycles,[274] in response to heatstroke,[275] and following NO administration[276] are available.

7.7 Glucose and Lactate

As outlined in section 4.6, the first reported biosensor was a glucose sensor developed by Clark and Lyons in 1962.[161] Despite the prolific research on such devices since this initial work, it was not until the mid-1970s that biosensors for direct applications in the living brain were reported. A glucose biosensor developed by Silver and co-workers was one of the first enzyme-modified electrodes demonstrated to be suitable for insertion into brain tissue.[277] The electrode was prepared by simply dipping a 0.1-μm diameter Pt-coated glass micropipette electrode into an aqueous solution of GOx. The electrode, operated at +600 mV (versus Ag/AgCl), had a response time of 2–3 s that later increased to >30 s when a protective nitrocellulose membrane was added. Because these were early first generation hydrogen peroxide detecting devices, there were difficulties in the quantification of the glucose concentration arising from fluctuating oxygen and/or AA concentrations.

Later, Boutelle et al. constructed a very stable GOx-modified electrode, based on the $TTF^{+}TCNQ^{-}$ electrodes of Albery et al.,[170] for applications in brain tissue.[278] GOx was immobilized by adsorption from solution. The electrode (250 μm) was held at 0 V (versus Ag/AgCl) and the signal from AA was found to decrease following both enzyme adsorption and implantation into brain tissue. Additionally, a differential method (involving the subtraction of the current recorded at an adjacent denatured enzyme electrode) was employed to minimize any possible interferences from fluctuating levels of AA. The response time of the sensor was of the order of 20 s, and no dramatic degradation of response was observed following 6 h periods of use in brain tissue. These biosensors were used to monitor glucose in the brains of freely moving rats and were shown to be capable of monitoring changes in glucose following a local application of insulin.

More recently, Silver and Erecinska have continuously monitored extracellular glucose in the brains of anesthetized rats in acute experiments with two types of substrate-specific microelectrodes (tips < 1 μm) in a number of different physiological and pathological conditions.[279] Electrodes used in normoxic brain were needle electrodes polarized at +600 mV (versus Ag/AgCl) and prepared by electrodeposition of Pt-black on gold or Pt surfaces. The enzyme was immobilized by dipping in a solution of GOx, air-dried and cross-linked on the metal with glutaraldehyde. Finally, the tips were coated with four thin layers of cellulose diacetate, dried and dipped in a solution of ascorbate oxidase (to reduce AA interference). In hypoxic studies, mediator glucose electrodes were used with ferrocene ($E^{0'}$, +165 mV versus SCE) as the electron acceptor. Extracellular glucose levels were shown to increase in hyperglycemia and decrease in hypoglycemia, paralleling changes in blood sugar. Increased neuronal activity, and in particular spreading depression, evoked triphasic alterations in the extracellular glucose concentration. Limitation in oxygen supply (hypoxia) led to a decline in the extracellular concentration of glucose with decreases to undetectable levels seen in ischemia despite the use of mediator electrodes. The extracellular concentration of glucose was estimated at 2.4 mM, in contrast to a value of 0.5 mM obtained using quantitative microdialysis.[280]

The electrochemical polymerization of a selective poly(*o*-phenylenediamine) (PPD) layer onto Pt electrodes has also recently been reported to produce interference-free sensors having a high enzyme activity and a fast response time (about 1 s), making them ideally suited to detecting analytes directly in brain ECF.[179,180] These sensors are generally prepared quite simply by potentiostatic polymerization from an enzyme/monomer mixture and operated at +700 mV (versus SCE) to detect the enzymatically produced hydrogen peroxide. Lowry and co-workers have reported a detailed characterization of Pt/PPD/GOx biosensors (125 μm) both in vitro[179] and in vivo in the striatum of freely moving rats.[180] Confirmation that these biosensors respond to changing glucose levels in vivo was obtained by i.p. injection of

insulin and local administration of glucose (via an adjacent microdialysis probe). Interference studies involved administering AA and subanesthetic doses of ketamine i.p. Both resulted in increased extracellular AA levels with ketamine also increasing oxygen. No significant change in the Pt/PPD/GOx signal was observed in either case indicating that changes in AA and oxygen, the principal endogenous interferences, have minimal effects on the response of these first generation biosensors. They also exhibited excellent stability in vivo and have been used continuously under chronic conditions (14 days). These results were attributed to a pre-implantation conditioning procedure[180] that helped overcome the general problem of loss of sensitivity (usually between 20–50%) following implantation. Furthermore, it was confirmed that depletion of analyte by the sensor was not a problem by examining the effects of perfusion, via an adjacent microdialysis probe, of drugs such as veratridine, that increases energy metabolism by stimulating Na^+/K^+-ATPase.[281] The same group also implanted combined biosensors and microdialysis probes into the striatum of freely-moving rats to determine the ECF concentration of glucose using a modification of the Lönnroth no-net-flux quantitative microdialysis technique.[281] A value of about 0.35 mM was obtained that is in good agreement with the value of 0.47 mM determined using microdialysis.[280] Recently Pt/PPD/GOx sensors have also been used to study the effects of mild hypoxia and hyperoxia,[282] neuronal activation (tail pinch),[208] and anesthesia on brain ECF glucose.[283]

Other recent work on ECF glucose monitoring using biosensors includes that of Hu and Wilson[284] who used a needle-type biosensor (~100 μm) to monitor changes in brain glucose in anesthetized rats. The sensor has a rigorous construction protocol involving Nafion®, cellulose acetate, bovine serum albumin, and polyurethane.[285] It had a response time of about 5 s and its usefulness was demonstrated by examining the time-dependent interstitial glucose concentration in the rat hippocampus in response to KCl depolarization and by stimulation of glutamate neurons through the perforant pathway. Shram et al.[286] have also reported the use of a glucose biosensor in the living brain. The sensor was constructed by immobilizing GOx onto the surface of a carbon fiber either by cross-linking with gluteraldehyde (the latter, in given conditions, was also covered with an additional membrane of Nafion® or cellulose acetate to eliminate proteins) or by enzyme entrapment in electropolymerized films of *m*-phenylenediamine. These glucose sensors were operated using DNPV and were reported to be insensitive to interfering substances such as AA. With properly chosen pulse parameters, the response to glucose resulted in a peak at a potential of about 1 V (versus Ag/AgCl) due to the oxidation of the enzymatically produced hydrogen peroxide. Extracellular brain concentrations were monitored in anesthetized rats during administration of insulin and glucagon. These sensors were later used in a detailed investigation of brain glucose in anesthetized rats under normal and hyperglycemic conditions.[287]

One of the principal motivations of the above work to develop and utilize a reliable, selective and rapid response glucose biosensor in the living brain is the fact that glucose is the major source of energy for the mammalian brain under normal physiological conditions. However, over the past few years there has been increasing evidence that lactate, synthesized and released by astrocytes, may also serve as an important energy substrate for neurons in the adult brain.[288] This prompted Hu and Wilson[289] to construct a lactate biosensor by substituting lactate oxidase for GOx in their original biosensor design.[284] The resultant sensor was used to monitor brain extracellular lactate in anesthetized animals and changes due to neuronal activity were examined in the dentate gyrus of the hippocampus after electrical stimulation of the perforant pathway. Shram and co-workers have also reported a lactate-specific biosensor based on a CFE coated with lactate oxidase.[290] Operated with their previously reported DNPV method for glucose[287] they performed preliminary in vivo experiments in the cortex of the anesthetized rat.

An interesting new approach to in vivo neurochemical monitoring that has also been applied to monitoring ECF lactate is the dialysis electrode reported by Albery and co-workers.[291] This system combines the advantages of in vivo monitoring using voltammetry with those of microdialysis: working, reference and auxiliary electrodes are inserted into the tip of a microdialysis probe and the chosen enzyme introduced by slow perfusion using a microdialysis pump (as in a conventional microdialysis experiment). This arrangement achieves the good sensitivity, time resolution and continuous output of an implanted electrode, with the added advantage that fresh enzyme or mixtures of enzymes can be added. The dialysis electrode is now available commercially (Sycopel International Ltd., UK) and has been used by Ikegami et al.[292] to monitor the concentration of extracellular lactate in the cerebral cortex of urethane-anesthetized rats. In addition to the lactate specific lactate oxidase, ascorbate oxidase was used to help eliminate AA interference.

7.8 Glutamate

L-Glutamic acid is a key excitatory amino acid neurotransmitter in the mammalian brain, and the measurement of ECF glutamate is a key step in elucidating its role in CNS physiological and pathological states. Although microdialysis collection with ex situ detection of glutamate has been widely used,[293,294] the ability to

monitor continuous real-time glutamate dynamics has only recently been realized due to the availability of the newly isolated enzyme, glutamate oxidase (GLUOx), and the development of GLUOx-modified electrodes. Because the concentration of glutamate in brain ECF (about 3 μM[295]) is much less than that for glucose, the problem of interference by reducing agents, especially AA, is more severe. Consequently, in comparison to ECF glucose, reports of brain glutamate monitoring with implanted biosensors have been more limited.

Wilson and co-workers have used glutamate sensitive microelectrodes to monitor changes in ECF glutamate in the brains of anesthetized rats.[296] Constructed in a similar manner to their glucose biosensor,[284,289] these devices also have underlying layers of both Nafion® and cellulose acetate to help eliminate interference problems. GLUOx and ascorbate oxidase were co-immobilized by droplet evaporation from a bovine serum albumin/glutaraldehyde solution. The sensor was operated at +600 mV (versus Ag/AgCl), had a rapid response time (about 1 s), and a high degree of sensitivity (<2 μM) and selectivity. Placement of the electrode in the dentate gyrus of the hippocampus led to the detection of both KCl-induced release of glutamate and release induced by electrical stimulation of the perforant pathway, despite a 50% decrease in sensitivity observed immediately following implantation in tissue.

A glutamate sensitive dialysis electrode (see section 7.7) has also been used for the continuous measurement of glutamate efflux in the brain of a freely moving rat following a 5-min tail pinch.[291] A Nafion®-coated Pt working electrode was held at a potential of +650 mV (versus Ag/AgCl) and the enzymatic production of hydrogen peroxide by GLUOx entrapped within the dialysis membrane monitored. Electrochemical interference from AA was eliminated through the use of ascorbate oxidase. The response time in vivo of this sensor was of the order of 1 min. Several other groups have also used this type of biosensor to monitor brain glutamate. Walker and co-workers monitored both glutamate and AA in rat hippocampus after perforant path stimulation in a study of epileptic discharge after seizure.[245] Asai et al. used a dialysis electrode to monitor extracellular glutamate in rat striatum and demonstrated two distinct phases of glutamate release during early severe brain ischemia.[297] The problem of oxygen interference under such conditions was assumed to be overcome by perfusion of the enzyme solution resulting in a stable oxygen supply at the reaction site on the electrode surface. Both latter studies were performed in acute preparations with response times of between 10–15 s. The Nafion® coating was replaced with a PPD layer to help further reduce interference.

More recently, a new glutamate biosensor has been reported that involves the simple entrapment of GLUOx on a platinum electrode surface (120 μm) with a PPD film, in a similar manner to that reported by Lowry et al.[179,180] for glucose. A detailed characterization in vitro of this sensor has been performed indicating similar characteristics to the Pt/PPD/GOx sensor, and suggesting ideal suitability for monitoring in vivo.[298] Preliminary experiments in vivo to detect extracellular glutamate in the awake, freely moving rat at 1 s intervals using a mild stressor (10-s tail pinch) have been reported for this device.[299]

Another analyte on which some preliminary monitoring in the brain has been performed using enzyme-modified electrodes is choline. Michael and co-workers developed amperometric biosensors for peroxide, choline and acetylcholine by immobilizing horseradish peroxidase (HRP), choline oxidase (CHOx), and acetylcholinesterase in a cross-linked redox polymer deposited on glassy carbon electrodes.[300] Co-immobilization of HRP and the model GOx was used to establish the feasibility of highly efficient bienzyme sensors at low substrate levels. Replacing GOx with CHOx produced sensors with submicromolar detection limits and a linear response up to 0.8 mM choline. Addition of acetylcholinesterase to the sensors generated a relatively small response to acetylcholine that demonstrated the feasibility of trienzyme sensors. Similarly prepared CHOx-electrodes based on 7 and 10-μm diameter CFEs have been used by the same group to monitor choline transients in vivo in the rat brain following local injection of choline near the electrode.[301,302] The electrodes were operated at −0.1 V versus SCE and exhibited a decrease in sensitivity of less than 25% following 5 h of exposure to brain tissue. The response time of all these sensors was less than 30 s, with 2 s response times achieved in some cases.

8 COMPARISON WITH BRAIN MICRODIALYSIS

As an alternative to VIV for neurochemical analysis in intact tissue, in vivo microdialysis involves the perfusion of the tissue (using a permselective membrane), collection of the dialysate, and subsequent analysis following separation (usually by HPLC or capillary electrophoresis). Electrochemical detection is often used to quantify the concentration of species present in dialysates, although other forms of detection are available, such as spectroscopic and refractive index measurements. Recent reviews of microdialysis methodologies cover issues such as comparison with other sampling techniques,[303] technological advances,[304–306] critical analyses of the physiological significance of species in the dialysate,[307–311] studies of peripheral physiology,[312] pharmacokinetics,[313–315]

calibration issues,[316] biotechnology applications,[317,318] behavioral studies,[319,320] and applications in the human brain.[321]

The microdialysis technique has been applied to humans in clinical studies, including head injury,[322,323] ischemia,[324,325] pharmacokinetics,[326,327] glucose metabolism,[328,329] neuromediator function,[330] and for monitoring during brain surgery.[331] The majority of these have been investigations of peripheral physiology, such as metabolite kinetics in skeletal muscle,[332] histamine release in skin,[333] and the effect of drugs[334] and physical exercise[335] on fat metabolism. The greater analytical certainty associated with cerebral microdialysis has also lead to clinical applications in the brain.[321,336] Of particular interest has been the role of excitatory amino acid neurotransmitters[337] and dioxygen[338] in the development of brain tissue damage following head injury. Neurochemical correlates of epileptic seizures have also been studied using the dialysis technique to quantify the involvement of glucose metabolism[339] and neuromediators[340,341] in this phenomenon.

An advantage of microdialysis is that a wide range of compounds – neuromediators, metabolites, amino acids, drugs, etc. – can be collected in each sample and separated reliably using recent advances in HPLC and electrophoretic technologies. The main disadvantages of dialysis at present are the relatively large probe size available (minimum about 200 μm) and the poor time resolution, ranging from 1–10 min. Voltammetry, on the other hand, has a more limited range of analytes, and often VIV studies are restricted to monitoring one analyte at a time. Its advantage of small probe size and high temporal resolution, however, allows investigations not possible with microdialysis.

ACKNOWLEDGMENTS

Financial assistance from Enterprise Ireland (Grant Nos. SC/98/450 and SC/99/149), University College Dublin and the National University of Ireland, Maynooth, is gratefully acknowledged. We are grateful to Dr Maddalena Miele for artwork (Figure 3).

ABBREVIATIONS AND ACRONYMS

AA	Ascorbic Acid
BBB	Blood–Brain Barrier
cAMP	Cyclic Adenosine Monophosphate
CEE	Carbon Epoxy Electrode

Fluorescence-based Biosensors

Clinical Chemistry **(Volume 2)**
Biosensor Design and Fabrication • Electroanalysis and Biosensors in Clinical Chemistry • Electroanalytical Chemistry in Clinical Analysis • Glucose Measurement

Electroanalytical Methods **(Volume 11)**
Neurotransmitters, Electrochemical Detection of • Pulse Voltammetry • Ultrafast Electrochemical Techniques

Since their introduction in the early 1970s, in vivo voltammetric methods have provided researchers with a means of studying the dynamics of neurotransmitter release mechanisms in whole animals and brain slices, and more recently in single cells in culture. Using microelectrodes (5–30 μm OD, outside diameter), generally made of carbon, investigators have studied the signaling dynamics of neurotransmitters and neuromodulators such as dopamine (DA), norepinephrine (NE) and serotonin (5-HT), and more recently nitric oxide (NO) and glutamate. Unlike the complimentary technique known as microdialysis, in vivo voltammetric methods allow for the very rapid (1–200 Hz) and spatially resolved (5–30 by 30–150 μm as compared to 200–300 μm by 1–4 mm) measurement of the dynamic properties of neurochemicals. However, the routine detection limits of such methods are in the 25–50-nM range for analytes such as DA, 5-HT and NO, and these do not rival the picomolar detection limits of methods used to analyze microdialysis samples.

These seemingly straightforward methods have been plagued by methodological problems, primarily dealing with the selective and sensitive measurements of neurotransmitters. Microelectrodes and associated recording techniques must be able to measure and identify selectively the analytes of interest without the use of powerful separation and quantitation methods such as high-performance liquid chromatography coupled to electrochemical detection (HPLC/EC). Improvements in microelectrode technologies and recording methods have greatly enhanced the utility of such methods for a variety of studies.

The purpose of this chapter is to give readers a general introduction to in vivo voltammetric methods that can be applied to studies of neurotransmitter and neuromodulator signaling dynamics in brain tissues and in cells in culture. We discuss the types of microelectrodes that are now used to record neurochemicals as well as surface modifications that are carried out on these microelectrodes to make them more sensitive and selective for different neurochemicals. The different recording methods and some of their inherent strengths and weaknesses are reviewed as well as the instrumentation currently used to record from microelectrodes for such measures. Finally, we discuss some of the applications of these methods and how they compare with other in vivo recording methods such as microdialysis and fiber optic sensors. This review does not focus on the biological systems that have been studied with these methods and the results of such studies. The major purpose is to give the reader an overview of in vivo voltammetry methods and how they can be used to study neurotransmitter and neuromodulator signaling dynamics in biological systems. Future developments in this field hold great promise for developing a large number of new microelectrodes for detecting a variety of neurochemicals in order to gain an understanding of chemical signaling,

which is an integral part of central nervous system (CNS) biology and all biological systems.

1 INTRODUCTION

The concept of using in vivo voltammetric recordings for the analysis of neurotransmitters and neurochemicals, such as DA, in the CNS was pioneered by Ralph Adams in the early 1970s.[1] The basic concept of the methodology is seemingly straightforward and is illustrated schematically in Figure 1. A voltammetric microelectrode is implanted in the brain region that contains the nerve endings, varicosities or dendrites of interest. More recently, this approach has been used in slices of brain tissue and in cell culture. Voltammetric recordings are carried out using a recording method with a sensitive potentiostat connected to the microelectrodes to measure the neurotransmitter of interest. Thus, the release of a neurotransmitter can be measured and related to the function of the CNS. Unfortunately, there are a number of methodological considerations that have needed refinement in order to carry out these seemingly simple measures reliably. In particular, the type of recording electrode and the choice of voltammetric recording method are critical for the rapid, sensitive, selective and reliable detection of certain neurotransmitters and neurochemicals.

During the 1990s, the techniques of FSCV, FCV and HSC were refined for rapid in vivo electrochemical measurement of neurotransmitters in brain slices and in the brains of mice, rats and monkeys.[2–12] In contrast to microdialysis techniques, which permit measurement of basal extracellular levels and slow (ca. 1–20 min) changes in extracellular monoamines and metabolites, electrochemical recordings using 5–30-μm diameter microelectrodes allow for rapid (1–200 Hz) measurement of neurotransmitters and neuromodulators in discrete brain nuclei.[2–14] In addition, such methods can dynamically monitor neurotransmitter release and clearance kinetics.[3–7] Using rapid voltammetric recording methods our laboratory and others have measured DA, NE and 5-HT release and uptake.[2–8,12,15–24] Improvements in recording methods have also allowed for the further identification of the detected neurotransmitter species, which has greatly increased the reliability of such measures.[2,3,7–9,12–25] Moreover, numerous laboratories have been using amperometric recordings to measure release of neurotransmitters from individual cells in culture.[26–32] Amperometric methods with modified microelectrodes have also been used to measure NO.[33,34] Finally, future developments in microelectrode

Figure 1 Schematic diagram illustrating the basic instrumentation needed to perform in vivo voltammetric recordings. Waveforms 1, 2, and 3 show the input potentials and output waveforms for high-speed chronoamperometry (HSC), fast-scan cyclic voltammetry (FSCV), and fast cyclic voltammetry (FCV), respectively.

technologies hold promise for routinely measuring other neurotransmitters and neurochemicals such as glutamate, lactate, glucose and γ-aminobutyric acid (GABA).[35–41]

This article is intended for those who want to gain a general knowledge of the principles, materials and techniques that underlie the current methodologies that are used to study CNS tissues and cells in culture using voltammetric methods coupled with microelectrodes. The current technologies that are used to measure neurotransmitters and neuromodulators, such as DA, NE, 5-HT, NO, glutamate and other neurochemicals, will be reviewed. We have endeavored to include mostly current data and references, but we have not tried to be comprehensive in our citation of all literature pertaining to this topic. There are additional reviews and review chapters that are recommended for those interested in the use of these methods.[2,12,25,42] We have undoubtedly omitted some important information, but we hope that this article will be of value to numerous scientists who want to use these methods to study the dynamics of neurotransmitters and neurochemicals in biological systems.

Scheme 2

2 ELECTRODES

As seen in Figure 1, the major tools that are used to carry out voltammetric recordings are microelectrodes that are implanted into CNS tissue or, in the case of single cell recordings, placed very close to the cells. The recording or working electrode is the electrode where the detection of the neurotransmitters or neurochemicals occurs. This is perhaps the single most important component of the recording system. A variety of different types of microelectrode, ranging in size from 5 to 200 μm in diameter, are used for such studies (see below). Reference and auxiliary electrodes are needed to carry out the measures without a drift in the potential that is applied to the working electrode.[43] A basic understanding of electrochemistry at solid electrodes can be obtained from Bard and Faulkner[43] or Adams.[44] Basically, as a function of the voltammetric method and the magnitude of the potentials applied to the electrode surface (see section 3), electrochemical reactions occur at the surface of the microelectrode. The basic oxidation reaction for DA is depicted in Scheme 1.

DA can be oxidized to form an *o*-quinone that under certain circumstances can be reduced back to DA. The reaction is a two-electron process. The oxidation reaction for 5-HT is rather different and again involves a two-electron reaction as seen in Scheme 2.

These reactions can occur at the surface of the working electrodes provided the voltammetric method (section 3) produces potentials at the microelectrode surface that are sufficiently large to cause the oxidation of these compounds and if the analyte is adjacent to the surface of the microelectrode. The current flow caused by these chemical reactions or faradaic current is proportional to the concentration of the analyte. While one equation cannot be used to describe the current response of all voltammetric recordings as they are related to the recording method (see section 3 and Bard and Faulkner[43]), the basic response of a large electrode at potentials > 100 mV beyond the oxidation potential for a given analyte can be described in Equation (1)

$$i = nFAC_bM \tag{1}$$

where i is the current measured, n is the number of electrons for a given chemical reaction, F is the Faraday constant, A is the total active recording surface area of the electrode, C_b is the bulk solution concentration of the analyte and M is a general purpose term encompassing mass transport of analyte to the electrode surface. In contrast to large electrodes, microelectrodes have both linear and spherical diffusion of analyte to the microelectrode tip and thus, if the response of the electrode is described accurately, an additional set of terms must be applied to model the electrode response completely.[45] However, to understand the basic concepts of the measurements, the current recorded is directly proportional to the concentration of the analyte or neurotransmitter (C_b), the active recording area of the probe (A), the number of electrons per molecule (n) and the mass transport of the analyte to the surface of the microelectrode. In an unstirred solution such as the extracellular space of the brain or in a quiet

solution next to a cell, a substitution can be made to Equation (1) to give Equation (2)

$$i = XC_b \quad (2)$$

where X, the calibration factor for a given microelectrode, can be determined pre- and/or postexperimentation by varying C_b and measuring i under solution conditions that mimic the extracellular space of the brain (artificial cerebrospinal fluid) or the media in which cells are studied. Thus, a hallmark of many voltammetric recording methods is that the electrodes respond linearly to changes in concentration of the analyte. This forms the analytical foundation for the use of these methods in biological systems.

Using the aforementioned terms, the i recorded from oxidation or reduction of an analyte, such as DA, is more accurately depicted for chronoamperometry (CA) using a modified form of the Cottrell equation seen in Equation (3).[45]

$$i = \frac{nFAC_bD^{1/2}}{\pi^{1/2}t^{1/2}} + 4nFr\pi C_bD \quad (3)$$

where t is the time of the measurement of i in seconds, D is the diffusion coefficient of the analyte, and r is the radius of the microelectrode.

The selectivity of recordings for the measurement of neurotransmitters such as DA in biological systems is a major issue. Modifications to microelectrode surfaces (see section 7) and the use of different recording methods (see section 3) have enhanced the selectivity of the voltammetric methods. In addition, selection of applied potentials can minimize interferents. However, voltammetric methods are inherently selective, as very few molecules in the extracellular space of the brain can be caused to oxidize or reduce. This is both an inherent strength and weakness of these methods. Although not comprehensive, Table 1 summarizes some endogenous and exogenous compounds that can be measured using voltammetric recording techniques using low or high oxidation potentials.[46,47] We urge caution because the actual oxidation potentials of these compounds are dependent on the recording electrode used, the recording method and any modifications of the microelectrode surface.

There are a variety of working, reference and auxiliary electrodes that are used to record neurotransmitters and neurochemicals. In the following sections we have tried to describe the basic compositions of the different electrodes and the advantages of each type.

2.1 Working Electrodes

The working or recording electrode used for in vivo voltammetric measurements in CNS tissues is generally fabricated to achieve a tip diameter of 5–200 μm, depending on the application. There are a number of types, and the choice of the size and type is often based on the molecule that will be measured and the recording preparation.

Table 1 Endogenous electroactive compounds and exogenous drug compounds that are electroactive, which are encountered in neurochemical studies[a,46,47]

Easy to oxidize	Harder to oxidize
DA	Melatonin
NE	Metanephrine
5-HT	Normetanephrine
Epinephrine	MHPG
DOPAC	5-HTP
L-DOPA	Tyramine
AA	Octopamine
5-HIAA	Tryptamine
Uric acid	Tyrosine
DHPG	Tryptophan
	Hydrogen peroxide
	NO
	3-MT
	HVA
	Neuroleptics: Clozapine, chlorpromazine
	Neuropeptides: Neurotensin, enkephalin
	Antidepressants: Imipramine, desipramine, mianserin
Catecholamine-related drugs: α-Methyldopa, α-Methyl DA, α-Methyl NE, Carbidopa	MAO inhibitors: Tranylcypromine, pargyline, α-methyl tryptamine
Other Drugs: Acetaminophen	β-Blockers: Sotalol, timolol, atenolol

[a] Compounds in bold are of most interest.
DOPAC, 3,4-dihydroxyphenylacetic acid; DOPA, 3-(3,4-dihydroxyphenyl)alanine; AA, ascorbic acid; 5-HIAA, 5-hydroxyindoleacetic acid; DHPG, 3,4-dihydroxyphenylglycol; MHPG, 3-methoxy-4-hydroxyphenylglycol; 5-HTP, 5-hydroxytryptophan; 3-MT, 3-methoxytyramine; HVA, homovanillic acid; MAO, monoamine oxidase.

2.1.1 Carbon Paste

Carbon paste electrodes are one of the oldest forms of electrodes used for in vivo electrochemical recordings in CNS tissues. They are formed by packing carbon paste into the end of a Teflon®-coated wire[48] or by using a mixture of carbon epoxy that is packed into a glass capillary.[45] Carbon paste is prepared by mixing powdered graphite with a hydrophobic material such as liquid paraffin, silicone oil, or wax. Stearic acid is sometimes added to the paste to improve the electrode's recording properties.[48] Graphite pastes can be mixed

with epoxy to form a graphite–epoxy mixture[45,46] or used as they are to make the Teflon® wire-type electrodes. A commercially available graphite–epoxy mixture is used for some types of graphite–epoxy electrodes (PX-grade Graphpoxy, Dylon, Industries, Cleveland, OH). The resulting electrodes have tip diameters of 100–250 μm, depending on the resulting diameter of the graphite–epoxy filled glass capillary or the diameter of the Teflon®-coated wire. While useful for certain applications, the size of these electrodes precludes their use for many applications.

2.1.2 Carbon Fiber Electrodes

Working electrodes made from carbon fiber or carbon monofilament are the most common and widely used forms of electrodes for CNS recordings. Basically, all of these electrodes are generally made by sealing one or more carbon fibers or carbon monofilaments in glass capillaries.[8,10,12,49,50] For certain single cell recordings, the fiber is sealed in plastic pipette tips.[51,52] Appropriate electrical connections to the fibers are made using silver pastes,[53] graphite pastes[8,10,54] or salt solutions.[55] There are numerous manufacturers of carbon fiber or carbon monofilament materials that range in size from 5 to 30 μm in diameter. Typical manufacturers and part numbers for popular fibers and one monofilament are as follows: 10-μm diameter (P-55, Amoco, Greenville, SC),[55] 7–8-μm diameter (type HM or XA-S, unsized, Courtaulds),[6,19] 8–12-μm diameter (SOFICAR, Paris France),[17] 30-μm carbon monofilament (#80036-001, Textron Systems Division, Wilmington, MA).[8,10] In addition, a number of companies sell prefabricated carbon fiber-based electrodes. Some of these are Quanteon, LLC (Lexington, KY), World Precision Instruments (Sarasota, FL), Dagan Corp. (Minneapolis, MN), ALA Scientific (New York, NY), MPB Electrodes (London, UK) and Axon Instruments (Foster City, CA).

Although often similar in size, the recording properties of different fibers can be quite different. This is attributed to the type of fiber and the methods and/or cleaning steps used to prepare the fibers. The degree of oxygen on the surface of the carbon will affect the recording properties of the fibers.[56] It is a good idea to use carbon fibers and carbon monofilaments that have been previously characterized. As stated, the fabrication steps are quite similar for different carbon fiber electrodes (CFEs); however, the choices of glass, connecting wire, cements and other materials can be quite diverse. Typical fabrication methods for a variety of fiber electrodes are given by various authors.[12,42,49,50]

One type of carbon monofilament-based electrode used for studies in our laboratory is constructed by cementing single ''as pyrolyzed'' 30-μm diameter single carbon monofilaments (#800036-001; Textron Systems Division, Wilmington, MA) inside a pulled glass capillary. A single glass capillary with a tip diameter of approximately 5 μm is pulled from a 2-cm length of (4.0-mm OD, 2.6-mm ID (inside diameter)) borosilicate glass tubing (Glass Warehouse, #26005) using a Narishige PE-2 puller. The tip of the pulled glass capillary is bumped to an inner diameter of 40–45 μm. A single carbon fiber (5 cm in length) is then passed completely through so that the fiber extends well beyond the tubing at both ends. A small drop of Epoxylite™ (The Epoxylite™ Corp., Westerville, OH) is placed on the carbon fiber at the exposed end of the glass capillary, and the fiber is then pulled into the tubing so that it is sealed well in the tubing with no excess Epoxylite™ on the exposed carbon fiber. This carbon fiber/glass capillary assembly is cured overnight in an oven set at 100 °C to dry the Epoxylite™. The open end of the larger tubing is then packed with a graphite–epoxy mixture (Graphpoxy™, Dylon Industries, Berea, OH) by smearing a layer of Graphpoxy™ on a microscope slide and tapping the back end of the electrode repeatedly through the Graphpoxy™ to the glass slide. It is generally not possible to fill the entire void with Graphpoxy™, but it is possible to see at least 3–4 mm of packed material through the side of the larger tubing. The tapping procedure results in breaking off the back end of the graphite fiber flush with the end of the larger tubing. The excess glass is cut off, exposing a glass capillary filled with Graphpoxy™ with a maximum OD of 500–750 μm. A 10-cm length of 36-gauge lacquer-coated copper wire is prepared by scraping 5 mm of coating from one end of the wire. The wire is then inserted into the back end of the larger tubing, through the Graphpoxy™. This results in a good electrical connection between the carbon fiber and the copper wire. Finally, a small drop of Epoxylite™ is placed on the copper wire at the point of attachment to the larger piece of glass tubing and the microelectrode is again baked overnight at 100 °C to cure the Graphpoxy™.

Once sealed in glass, the carbon monofilament or CFEs can be configured for a variety of applications. They are either cut and sometimes polished to form an oval disk electrode[57] or trimmed to form a short cylinder (30–150 μm in length), which is perhaps the most popular form of CFE. A scanning electron micrograph of the tip of a 30-μm diameter cylindrical tip carbon monofilament electrode is shown in Figure 2. In addition to the extended cylinder, the tips of the electrodes can be etched or the electrodes can be electrically pretreated to enhance their recording properties.[17]

2.1.3 Carbon Arrays

A novel type of array electrode that holds promise for future applications is manufactured using semiconductor

Figure 2 Scanning electron micrograph of the tip (30-μm OD, cylindrical tip) of a single carbon monofilament microelectrode. The scale bar is 10 μm.

fabrication techniques on substrates of silicon. The potential advantages of array electrodes include: (1) reproducible recording sites, (2) the ability to record from multiple brain sites from a single probe, (3) spatially defined recording sites for recording from layered brain structures, (4) the ability to stimulate and record single unit or chemical activity electrically from the same recording sites, and (5) reduced cost compared to handmade electrodes. These electrodes have been characterized[58] and used in vivo.[59] Briefly, these electrodes are fabricated using photolithography to pattern recording sites, connecting lines and bonding pads on to an insulated silicon surface. The metalized connecting lines are insulated and then the recording sites are sputter-coated with carbon. At present, the recording characteristics of the carbon-sputtered multisite probes are worse than single carbon fiber microelectrodes.[58,59]

2.1.4 Noble Metals

Platinum (Pt) or platinum–iridium (Pt–Ir) wires, often sealed in glass, form the foundation of a number of electrodes that are being developed to measure other neurotransmitters and neurochemicals by using oxidative enzymes attached to electrode surfaces.[35–41,60,61] These microelectrodes can be made ranging from 5 to 250 μm in diameter. In general, Pt and Pt–Ir are not ideal surfaces for measuring molecules like DA, NE and 5-HT. However, they are excellent for measuring peroxide formed from oxidative enzymes or enzyme cascades. A particularly unique type of recording electrode has been developed that is actually a combination of a microdialysis probe and a platinum electrode and has a 230-μm OD. These electrodes are called dialysis electrodes and they are sold by Sycopel International Ltd (Tyne and Wear, UK).[62] They are very versatile, as they can be filled with a variety of oxidative enzymes to make them sensitive to a number of analytes, such as glutamate and lactate.

2.2 Reference and Auxiliary Electrodes

A stable reference is an important element of the electrochemical measurement because the potential of the working or recording electrode is changed relative to a stable reference electrode. By contrast, many laboratories do not use an auxiliary electrode, because of the small currents and low impedance of the recording solutions. However, some instruments still work in a three-electrode (auxiliary, reference, working) versus two-electrode (reference, working) mode. Generally miniature forms of reference electrodes and auxiliary electrodes are used so that they can be directly implanted into CNS tissue. However, for brain slice and single cell recordings, standard size reference electrodes are often employed.

2.2.1 Ag/AgCl Reference Electrodes

The miniature Ag/AgCl electrode is the most common reference electrode used for voltammetric recordings in CNS tissues.[4,6,10,15,20] These can be made by using a short length (4–6 cm) of Teflon®-coated (250-μm OD) silver wire. The Teflon® is removed from 3–5 mm on one end. A voltage of +0.5–+1 V is applied to the Ag wire that is submerged in 1-M HCl for about 5–10 min using a platinum wire as the cathode. The Ag/AgCl reference should be a silver gray color. A standard size Ag/AgCl reference that is used for slice and single cell recordings is the RE-5 (BAS, Bioanalytical Systems, Lafayette, IN).

2.2.2 $Hg/HgCl_2$ Sodium Saturated Calomel Electrodes

The sodium saturated calomel electrode (SSCE) is a less popular reference, but it is still used.[12] Mercury is in contact with a solution that is saturated with mercury(I) chloride and NaCl. These can be made in-house or purchased from private manufacturers.

2.2.3 Auxiliary Electrodes

As previously stated, auxiliary electrodes are not always used for voltammetric recordings with microelectrodes. A standard auxiliary electrode is a Teflon®-coated silver wire (250 μm diameter) that has 3–5 mm of the Teflon® removed from one end. This is placed in contact with brain tissue or cell supernatant, or for whole animal recordings the Ag wire is connected to the skull via a screw that is in contact with the dura. Alternatively, a stainless steel wire in contact with CNS tissue or the perfusion medium is used.[24]

3 RECORDING METHODS

The choice of recording method is perhaps the single most confusing aspect of voltammetric recordings in CNS

tissues and cells. In this section we have tried to explain the different recording methods and how they have been used to study neurotransmitters and neurochemicals in CNS tissues and single cells. The methods are all based on the way the potential is varied at the working electrode to record the oxidation or reduction of analytes, such as DA. Basically, as depicted in the inset to Figure 1, recording methods usually involve applying voltages to the working electrodes using square waveforms, triangle waveforms or a combination of triangles and squares. In addition, the voltage can be constantly applied for certain applications. The choice of the recording method for a given study will depend on the temporal resolution, potential confounding substances, the size of the electrode needed and the sensitivity required for the measurements. In addition, the availability of instrumentation to perform the different methods and personal preferences must also be considered.

3.1 Amperometry

Amperometry involves the measurement of current at a constant fixed potential and is the simplest of the electrochemical techniques. The current can be monitored continuously therefore this technique has the ability to record events that occur very fast (200–1000 Hz). In addition, since the voltage is applied to the working electrode constantly, the nonfaradaic background current recorded from the electrode is very low, allowing for very sensitive measurements. Amperometry is used with HPLC/EC systems, which accounts, in part, for the high sensitivity of these methods. Amperometric recordings, because of the high sampling resolution, are used to study catecholamines released from single cells.[27–32,63] In addition, amperometry is useful for measuring compounds such as hydrogen peroxide, NO, and ascorbate. Hydrogen peroxide is of interest because it is the product of oxidase enzymes such as glutamate oxidase.[35–40] Enzyme modified electrodes will be discussed later.

The danger of fixing the potential is that analytes and analyte oxidation products readily adhere to the electrode. This poisoning of the electrode changes its recording properties. Also, when using a fixed potential the source of the analytical signal cannot be determined because any species that is electroactive at the potential applied to the working electrode will contribute to the current (see Table 1). Cahill and Wightman overcame this problem by the use of two electrodes to differentiate between ascorbate and catecholamines.[64] The first electrochemically modified carbon fiber potential was set at +0.05 V versus SSCE. This electrode was selective for ascorbate. A second unmodified CFE was set at +0.65 V and detected ascorbate and catecholamines. Currents obtained from both electrodes were used to determine the species being released from bovine adrenal medullary cells. Thus, a combination of electrodes can be used to overcome some of the limitations of amperometry. However, in general, amperometric recordings are used to study very rapid (<1 s) release of catecholamines from single cells and to carry out studies of NO and measures involving oxidase enzyme-based electrodes in CNS tissues.

3.2 Chronoamperometry

CA is one of the oldest methods used for in vivo electrochemical measurements in CNS tissue and is based on the work of Cottrell, as discussed by Bard and Faulkner.[43] An applied potential is instantaneously stepped from a resting value to a higher potential that is usually 50–100 mV in excess of the oxidation potential of an analyte. The potential is held at this higher value for ca. 1 s then it is stepped back to the resting potential. Current is measured after the potential has been stepped, during the time that the nonfaradaic background current of the electrode has declined (ca. 100 ms). Current increases dramatically as the potential is stepped from its resting value. This is caused by the charging current of the electrode and the electroactive species that is being oxidized. The charging current decays with time as the potential is held at its higher value (see Waveform 1 in Figure 1). An advantage of this method is that the current recorded from the analyte is directly proportional to the concentration of the analyte and therefore the current can be summed or averaged over most of the measurement, once the charging current has declined for ca. 5–20 ms. Another advantage of this method is that the background charging current of the electrode is a minor component of the signal, which enhances the signal-to-noise of the recording method. These square wave potential steps have been repeated at 60-s intervals to monitor events that occur as a function of time using stearate-modified carbon paste electrodes. Typical resting and applied potentials were −0.15 V and +0.25 V versus Ag/AgCl reference, respectively when using stearate-modified carbon paste electrodes to measure extracellular DA.[65–67]

3.2.1 High-speed Chronoamperometry

High-speed chronoamperometric recordings are a rapid version of the aforementioned methods originally described by Cottrell.[43] They have been used to measure DA, NE, 5-HT and NO in a variety of preparations. These methods are advantageous because they are rapid, sensitive and record data that can be used further to identify the detected compound(s).

A carbon fiber microelectrode is held at a resting potential of −0.20–0.0 V versus Ag/AgCl reference; electrochemical recordings are made in a suitable buffer

solution to simulate CNS tissue. The voltage is then instantaneously stepped to an oxidation voltage of +0.45–+0.55 V. This voltage step is chosen to exceed the oxidation potential of the potential analyte, in this case the biogenic amine neurotransmitters such as DA and 5-HT, by at least +0.10 V. This produces a rapid change in the current recorded by the microelectrode that rapidly decays as a function of time. This charging current is allowed to decay for 4–20 ms before the background current of the microelectrode is measured. The square-wave voltage step is held at the oxidation voltage for a fixed time period of 20, 50 or 100 ms, during which the oxidation current is sampled for 15, 40 or 80 ms. The square-wave voltage step is then instantaneously returned to the resting potential. Similar to the case of the first oxidation step, the return of the potential to the resting voltage produces a reduction reaction at the surface of the electrode. A rapid decrease in the reduction current represents the charging current of the recording and this is allowed to decay for 4–20 ms. The resting voltage is maintained for a fixed period that is identical to the prior square-wave step of 20, 50 or 100 ms. Like the oxidation current step, the current is sampled for a fixed time period of 15, 40 or 80 ms. In our studies, a 50-kHz sampling rate is employed to measure the oxidation and reduction current portions of the signals. As the current is integrated, the correct term for this type of recording is high-speed chronocoulometry.[8] The symmetric voltage steps are continued at a set time period to produce signals with a sampling resolution of 5 Hz (100-ms oxidation, 100-ms reduction; 5 per second), 10 Hz (50-ms oxidation, 50-ms reduction; 10 per second) or 25 Hz (20-ms oxidation, 20-ms reduction; 25 per second). In theory, the signal-to-noise ratio of such recordings is greatly enhanced because small changes in current due to the detection of an analyte are not masked by large background current. In addition, potential changes in the background current of an electrode that do not relate to increases or decreases in an analyte are potentially less prone to produce recording artifacts, owing to the lower background current levels. Typical detection limits for DA and 5-HT are 25 nmol using a 30-μm diameter carbon cylinder electrode.[68–70]

In a similar way to FSCV methods (see below), HSC recordings yield information regarding the major contributor to the electrochemical signal.[8,68–70] The detection of DA yields reduction to oxidation (red/ox) current ratios with Nafion™-coated electrodes between 0.5 and 0.9 depending on the thickness of the Nafion™ film and the drying temperature of the Nafion™-coating procedure.[8,10,68–70] In contrast, AA produces red/ox ratios of 0.0 and 5-HT produces ratios of 0.0 to 0.2.[8,15,18,68–70] Thus, somewhat analogous to the waveforms seen with FSCV (see below),[7,12] DA, AA and 5-HT produce distinctive red/ox ratios which can be used further to identify the detection of these compounds in brain tissue.

Many recordings in CNS tissues and other applications do not require temporal resolutions of 5–25 Hz. Therefore, for more standard recordings, the signals are averaged over a 1- or 2-s time period.[8,68–70] This further enhances the signal-to-noise ratio of the recording methods and decreases the number of data points that must be stored by a microcomputer recording system.

3.2.2 Double Potential Step

Double potential step CA or differential pulse amperometry (DPA) involves stepping the potential from a resting potential to a higher potential that oxidizes easily oxidizable, interfering species such as ascorbate. The current measured at this time is a result of the background current and any easily oxidized interfering species. The potential is again stepped to the final potential. The current measured at this point is caused by the background, interfering species and analyte. The difference in current between the prepulse and final potentials is recorded. In this way, the contribution due to the background and interfering species can be minimized. The main drawback of DPA is the lower temporal resolution compared to FCV or HSC (scan rate = 1 Hz). Using DPA, DA can be measured with untreated CFEs using a resting potential of −240 mV and a final potential of +200 mV. The measuring pulse duration was 400 ms with a measuring pulse amplitude and prepulse duration of 50 mV and 100 ms, respectively.[17,70] The electrodes were 50 times more sensitive to DA than AA and the detection limit was 0.5 μM. Electrochemical pretreatment of the electrodes was seen to lower the detection limit to 5 nM at the expense of a great decrease in response time (10–30 s).

3.3 Cyclic Voltammetry

In cyclic voltammetry (CV) the current is measured as the potential is steadily ramped up from a starting potential to the switching potential where it is ramped down to the starting potential (see the triangle wave 2 in Figure 1). The scan rate is typically between 10 and 300 mV s^{-1}. CV is classically used as a qualitative technique for determining red/ox potentials and diffusion coefficients of molecules. Typically the starting potential is lower than the oxidation potential of the analyte of interest (ca. −0.5–0.0 V). In an unstirred solution, as the potential becomes more positive the recorded current becomes more negative as the electroactive species begins to be oxidized. If the electrode is large enough a peak will be seen at the oxidation potential due to depletion of the electroactive species near the electrode surface. If the electrode is small, a plateau will be seen because spherical

diffusion will be sufficient to bring fresh molecules to the electrode surface to be oxidized. After the potential ramp is reversed, the current begins to rise as the oxidized species that has not diffused away from the electrode begins to be reduced. If the electrode is sufficiently small, no reduction peak will be seen because all of the reduced species will have diffused away from the electrode surface. While used as a tool to characterize working electrodes, normal CV is rarely used for in vivo electrochemical recordings due to its slow recording rates. For a complete discussion of CV refer to Bard and Faulkner.[43]

3.3.1 Fast-scan Cyclic Voltammetry (Triangular)

FSCV uses the same triangular-shaped ramps in potential as normal CV but at very high scan rates. This is one of the most popular in vivo voltammetric methods due to its excellent sensitivity, time resolution and compound identification capabilities.[3,7,12,14,16] Typical resting and switching potentials are −0.4 and +1.0 V, respectively, for DA. With FSCV, much higher scan rates are used compared with CV (300–900 V s^{-1}). The high scan rates are coupled to 10-Hz repetition rates to track rapid biological events. However, high scan rates cause large background currents, which can increase the limit of detection (LOD). To obtain an analytically useful signal, the voltammograms are background-subtracted to make the analyte peaks (faradaic current) apparent. A background voltammogram or series of voltammograms is selected and subtracted from subsequent scans during a recording session.

Repetitive CVs, often 10 Hz, are sampled to obtain time-dependent concentration profiles. The current is averaged over a desired potential range corresponding to oxidation (or reduction) of the analyte. The interval between successive scans is at least 5–10 times the duration of each individual scan to allow the diffusion layer to return to its prescan state. Typically analytes are sampled up to approximately 8 μm from the electrode surface.[12]

The voltage ranges of the oxidation and reduction peaks on the voltammograms or the shapes of the voltammograms can be used to identify compounds that are responsible for a given signal. As with HSC, the ratio of the oxidation and reduction peaks can be used to help identify the analyte. In addition the number of peaks can be used to identify the source of the sensor response. Although their oxidation peaks were overlapping (+0.53 V), DA was distinguished from 5-HT because DA had a single reduction peak at −0.18 V but 5-HT had two reduction peaks at −0.05 and −0.56 V. A dual wave triangular potential was used with resting and switching potentials of −0.7 and +1.3 V, respectively. The scan rate was 813 V s^{-1} and the triangular waveform was repeated at 4 Hz.[71,72] In another recent report, three-dimensional plots of voltage versus time with current plotted in false color were used to visualize the source of the sensor response. This was useful for distinguishing between DA, 5-HT, and pH changes during FSCV recordings.[73]

Measurements of DA using FSCV have been shown to be dependent upon divalent cation concentrations such as Ca^{2+} and Mg^{2+} and changes in pH.[12,74] Also, the oxidation of DA with double potential step CA and CV yields higher currents than would be expected from a species that was free to diffuse away from the electrode following oxidation.[75] These studies support the hypothesis that oxidation of DA at CFEs involves significant adsorption of the analyte. Unlike FSCV, HSC does not seem to be affected by changes in divalent cations and no effects from pH changes have been reported.[8,68–70]

DA has been most extensively measured using FSCV. In addition NE and 5-HT have been quantified.[3,12,14,16,76] Recordings for NE are inherently less sensitive than those for DA.[12] Also NE gives a similar waveform signature to DA. 5-HT is readily discerned from NE, DA and other neurochemicals. In contrast to DA where the scan rate was 300 V s^{-1} and the resting and switching potentials were −0.4 and 1.0 V, respectively, the potential was scanned from 0.2 to 1.0 to −0.1 to 0.2 V with a scan rate of 1000 mV s^{-1}.[3,76] By using this alternate waveform and scan rate the follow-up reaction where surface adsorption occurs was minimized. Nafion™-coated electrodes were 20 times more sensitive to 5-HT than DA. Typical detection limits for DA and 5-HT are 25–50 nM with these methods. Finally, histamine and oxygen can be quantified using FSCV.[12,77]

3.3.2 Fast Cyclic Voltammetry ($1\frac{1}{2}$ Triangle)

Another approach involving CV recordings uses a triphasic ramp voltage as the waveform (see Waveform 3 in Figure 1).[20,22–24,78] This technique has been called $1\frac{1}{2}$ triangle or FCV. With this "W"-shaped waveform the potential decreases from the resting potential to a lower potential. The potential then increases to the switching potential, which is higher than the resting potential. The potential is finally ramped down to the lower potential then back to the resting potential. Each scan typically lasts 15–20 ms and the scan rate is 300 V s^{-1} or higher. The frequency of scans is usually 1 Hz. The resting, lower, and upper potentials are 0, −1, and +1 V, respectively. Using this approach, DA has an oxidation peak at +0.6 V and a reduction peak at −0.2 V at certain carbon fiber microelectrodes.[79] With this waveform the detection limit of such electrodes has been reported to be about 200 nM. Increased sensitivity for DA has been shown when the upper potential was increased to +1.4 V, which was attributed to increased analyte adsorption and activation of the carbon surface.[80]

3.3.3 Sine-wave Cyclic Voltammetry

Another CV method involves the use of sine wave driving voltages. Sine wave-based CV techniques are those that involve using a nonlinear scanning input voltage instead of the linear ramps and pulses used in other techniques. The slopes of the voltage ramps are constantly changing and the potential is essentially held at the switching potentials instead of being rapidly switched. The first example is continuous scan cyclic voltammetry (CSCV). CSCV was developed to increase the temporal resolution of voltammetry. The input voltage was a 100-Hz sine wave with a peak potential of +1.0 V and a minimum potential of −0.5 V. Background subtraction was again used and the current was sampled every 10 ms. An advantage of CSCV over FCV is that fast scan rates can be used without losing sensitivity. Sample and hold circuits were used and set at +0.59 and −0.27 V for measuring DA. Some microelectrodes were able to detect DA with a detection limit of 10 nM.[81] Interestingly, investigators have not taken advantage of the AC signal properties of these recordings to increase sensitivity or to further identify analytes.

The second example involves a triphasic sine wave like that used with FCV. The triphasic sine wave (2 Hz) was used to overcome the artifact seen when the polarity of a linear potential ramp is switched. The resting, upper and lower potentials were 0, −1, and +1.3 V, respectively. The potential followed a sinusoidal wave down to the lower potential where it climbed to the upper potential. The sine wave went to the lower potential then back to resting potential. DA yielded single oxidation (+0.6 V) and reduction peaks while NO showed a single oxidation (+1.2 V) and two reduction peaks. DA and NO were quantified simultaneously by following the current at their respective oxidation potentials with little cross-talk. The reduction peaks were used to identify the analytes.[82] The sine-wave techniques have the advantage of reducing instrumental artifacts caused by the rapid switching of potentials when using high scan rates with the triangle waveforms.

3.4 Linear Sweep Voltammetry

In linear sweep voltammetry (LSV) current is measured while the voltage is steadily ramped, usually at slow rates of 10–20 mV s^{-1}. Using some electrodes, a peak is observed for an electroactive species in unstirred solutions caused by depletion of the species near the electrode. The electroactive species is only partially replenished by diffusion. The linear sweep is applied at regular intervals (ca. 5–10 min) and is not a fast recording technique. A semiderivative circuit is used to improve the resolution between peaks for LSV. Although LSV and semiderivative LSV[48,83] have been used to track in vivo changes in neurotransmitters, the speed of the technique limits its utility for many applications.

3.5 Rotating Disk Recordings

Rotating disk electrode voltammetry (RDEV) has been applied to measuring uptake and release of neurotransmitters, such as DA and NE, in brain tissue minces and cells in culture. RDEV is unique because larger glassy carbon electrodes (3 mm) are used and the electrode actually stirs the sample solution. A constant potential is applied to the electrode which is usually >100 mV past the peak oxidation potential of the analyte of interest. The analyte is brought to the working electrode surface by a constant stirring motion produced by spinning the electrode at a constant rate. The Levich equation can be used to describe the response of the electrode.[43] These techniques have been applied to studying the kinetics of neurotransmitter uptake in tissue pieces and cell suspensions.[84,85]

Using these methods, DA was measured as the limiting current recorded at a glassy carbon RDE (rotating disk electrode) at an applied potential of +0.45 V versus Ag/AgCl reference. The rotation was 2000 rpm.[84] Both NE and DA have been measured in cell suspensions using RDEV.[85] In another study, a two-electrode system was employed to measure two analytes. DA and *m*-tyramine transport in cell suspensions was investigated using two RDEs. The potential of the first electrode was held at +0.4 V versus Ag/AgCl reference. Current measurements at this electrode corresponded to the oxidization of DA alone. The second electrode's potential was set at +0.65 V to measure both DA and *m*-tyramine, with both electrodes rotating at 4000 rpm.[86]

3.6 Differential Pulse Voltammetry

In differential pulse voltammetry (DPV), there is a linear ramp in potential with superimposed steps in potential that happen at regular intervals.[17,43] The current is measured for short time periods before and at the end of each pulse. The difference between these is plotted versus potential to yield voltammograms with pronounced peak shapes. The power of this technique is in resolving between compounds with similar oxidation potentials. The drawback of DPV is the temporal resolution: about one scan per minute.

DPV has been used to measure DOPAC in both the nucleus accumbens and striatum in the rat CNS with two electrically pretreated pyrolitic 12-μm CFEs.[87] One scan was completed every 5 min, as the potential range was −0.2–+0.35 V with a scan rate of 5 mV s^{-1}. The pulse amplitude was 50 mV with a frequency of 2 Hz. Individual oxidation peaks were observed for AA, catecholamines, indolamines, and uric acid. The separation of different

compounds is a clear advantage of this methodology. However, its slow sampling rate precludes the use of DPV for many applications.

3.7 Differential Normal Pulse Voltammetry

Differential normal pulse voltammetry (DNPV) involves stepping the potential from a resting potential to a higher potential then stepping the potential to a slightly higher potential. The potential is returned to the resting potential and the previous potential steps are repeated while sequentially increasing the step size. The difference between the prepulse and final potential values is recorded. The advantage of this technique over DPV is that the potential returns to the resting potential between measurements.[88]

DNPV has been used to measure DOPAC.[89] A scan was completed every 2 min from −0.26 to +0.16 V versus Ag/AgCl reference. The scan rate was 3–4 mV/0.4 ms with a prepulse duration of 70–80 ms. The pulse duration was 40 ms and pulse amplitude was 30 mV. The detection limit for DOPAC was 1 μM at a potential of +0.055 V. Dihydroxyphenylethylene glycol (DOPEG) was detected at +0.08 V (LOD = 0.3 μM).

4 INSTRUMENTATION

The measurement of neurotransmitters and neurochemicals with microelectrodes requires specialized instruments capable of making often fast, repetitive (1–1000 Hz) and low-noise current measurements. Typical currents are in the low picoampere to mid-nanoampere range. There are no commercial instruments available that are capable of performing all of the aforementioned methods. We have tried to identify instrumentation that has the capability to carry out many of the different electrochemical recording methods.

4.1 Commercial

Several companies sell very versatile potentiostats that are often controlled by Windows-based software. Some of these are: Bioanalytical Systems – BAS 100B/W and CV-50W (West Lafayette, IN), Radiometer Analytical S.A. – Volta Lab 40 (Lyon, France), EG&G Princeton Applied Research – Model 394 (Wellesley, MA), and Cypress Systems, Inc. – CS-1200 (Lawrence, KS). These are all computer-controlled electrochemical analyzers capable of performing amperometry, CV, LSV, CA and a variety of other electrochemical methods. However, these instruments are more suited to microelectrode characterization studies, as they cannot perform many of the fast cyclic waveforms and currently they are not capable of analyzing and storing repetitive measures at 1–100 Hz recording rates.

Axon Instruments, Inc. (Foster City, CA) produces a potentiostat called the Gene Clamp 500 that is ideal for fast amperometric recordings. This system can be linked to commercially designed software for data analysis and storage. In addition, the Dagan Corporation (Minneapolis, MN) makes the Chem-Clamp that is suitable for amperometric recordings. There are additional commercial patch-clamp amplifiers that can be used for amperometric recordings. These amplifier systems are generally used for single cell recordings involving very rapid (<50 ms) current measurements.[26–32,90]

Several companies market systems designed for high-speed in vivo electrochemical measurements. All of these instruments are optimized for rapid recordings using microelectrodes, but they cannot perform all of the aforementioned methods. SOLEA Tacussel (Villeurbanne, France) makes the Biopulse, which is an analog instrument for carrying out DPV, DNPV and DPA measurements. Cypress Systems sells the EI-400, which is a low-noise potentiostat that is generally used for FSCV measurements. It now has an internal waveform generator and custom, Windows 98-based software is available. P.D. Systems (West Molesey, Surrey, UK) sells the Millar Voltammeter, which is an analog system designed primarily for FSV recordings. GMA Technologies, Inc. (Vancouver, Canada) markets a microcomputer-controlled potentiostat called the E-Chempro electrochemical instrument. This instrument can carry out LSV and CA recordings. Harvard Apparatus (Holliston, MA) now markets the IVEC-10, which is a microcomputer-controlled system for performing HSC, FSCV, FCV and amperometry. This system is a ''turn-key'' microcomputer-controlled potentiostat that has menu-driven software that is very easy to use. The current availability and capabilities of all of the aforementioned instruments should be gained from the manufacturers and laboratories that use these instruments.

4.2 Laboratory Designed

Many laboratories build or modify their in vivo electrochemical recording systems. The typical laboratory-designed system consists of a two-stage amplification system, a general-purpose potentiostat, an external waveform generator (if required), and an output device such as a strip chart recorder, sample and hold amplifier, and/or a microcomputer. The preamplifier is located as close as possible to the microelectrodes to minimize noise. The second amplifier is often located within the potentiostat. Software can be written or commercially available programs can be employed to store the data. External waveform generators can cause excessive noise in these

systems, therefore proper grounding and shielding must be used.[12,49] Low-pass filtering can be used to eliminate high-frequency noise. This can be done using analog filters or can be carried out digitally using microcomputer software.

5 PREPARATIONS

By far the largest number of voltammetric recordings in CNS tissues have been carried out with respect to the nigrostriatal and mesolimbic DA pathways in the CNS of rats, mice, monkeys and guinea pigs.[1,2,4–7,9–14,16–20,22] Voltammetric measures of DA have involved studies of electrical stimulation of the medial forebrain bundle and the effects of drugs that alter DA neurons in anesthetized rats and more recently in free-moving rats.[7,12,14,16,20,22,42,57] The low extracellular levels of DA, NE and 5-HT have limited voltammetric studies of resting levels or basal levels of the neurotransmitters, which can be carried out with microdialysis methods. This has resulted in the extensive use of electrical and chemical stimuli to cause the release of DA so that it can be reliably measured. In contrast to the extensive number of studies of DA, there is a growing body of data regarding NE and 5-HT release from brain areas of the rat such as the hippocampus, substantia nigra, raphe nucleus, cerebellum, locus coeruleus and the dorsal raphe.[3,6,8,17,19,21,23]

5.1 Cells in Culture

Wightman et al.[91] introduced the concept of using fast amperometric recordings to study release of neurotransmitters, such as NE, from single cells. This is a rapidly growing area of study that uses $\leq$5-μm diameter disk recording electrodes coupled with amperometric or FSCV recordings to study properties of quantal release from individual cells in culture. A number of studies have been carried out on PC-12 cells, adrenal chromaffin cells, mast cells and engineered cells.[26–32,63,91] These studies demonstrate the very rapid recording capabilities of the amperometric recording methods. Although it can be argued that many of these cells are not necessarily good models of CNS neurons, a variety of mechanistic studies are being carried out to understand further the fundamental properties of exocytotic release.

5.2 Brain Slices/Tissue Pieces

Perhaps one of the most rapidly growing areas using voltammetric recording techniques involves the use of brain slices from rats and mice. This methodology has a number of advantages over studying the CNS using anesthetized or freely moving animals. First, the slice preparation allows for visual control of all electrode placements. This is particularly advantageous when one is studying layered structures such as the hippocampus and hard-to-hit nuclei such as the substantia nigra and the dorsal raphe.[3,6,8,19,70] Secondly, the slice preparations can be superfused with known concentrations of drugs for pharmacological studies. Third, the slice preparation makes it easier to study the brains of smaller animals such as mice. Finally, the slice preparation is unanesthetized tissue. Disadvantages involve the fact that outputs and inputs to brain structures are severed and that the viability of the slices can be a problem.

5.3 Whole Animals

Anesthetized rats have been used extensively to study the dynamics of DA neuronal systems using voltammetric techniques.[4,5,13–18,25,42] Potential disadvantages of this preparation are the effects of anesthesia on the measurements and the inability to know the exact concentrations of drugs that affect CNS function. However, the anesthetized preparation is still powerful for studies of the more intact CNS.

The other major preparation for voltammetric studies involves the use of freely moving animals. In these studies the recording electrodes are often implanted days prior to measurement or a microdrive cannulae system is attached to the skull of the rat.[7,10,11,22,48,64–66,92] These measurements often involve the use of special miniature potentiostats that are placed close to the animal's head.[7,22,93] Studies have been carried out to measure electrically-evoked release of DA and potassium-induced release of DA. In addition, a number of studies in freely moving rats have been carried out regarding the effects of drugs of abuse, such as cocaine and amphetamine. These studies are very time-consuming compared with brain slice or cell culture studies, but hold the promise of understanding more of the underlying properties of neurotransmitter signaling in freely moving and behaving rats.[93,94]

6 APPLICATIONS

The majority of in vivo voltammetric studies involves the insertion of the microelectrodes into the brain regions of interest in the intact brain or brain slices (see Figure 1). In the case of cells in culture, the microelectrodes are positioned as close as possible to individual cells. Voltammetric measurements are then started to achieve a stable background. Once stable measurements are recorded, the effects of an event such as electrical stimulation or chemical stimulation of the neurons or

cells is triggered and studied. Additional events are triggered to determine the effects of drugs used to alter the neuronal systems. The numerous applications and results obtained with these methods are beyond the scope of this article. We suggest that the interested investigator should read additional review articles and book chapters that concentrate on applications of this technology.[2,12,42]

6.1 Release of Neurotransmitters and Neurochemicals

The major reason for the development of in vivo electrochemical recording methods was to measure the release of neurotransmitters such as DA, NE and 5-HT in the intact CNS. Because of the very low basal release levels of these neurotransmitters, the majority of in vivo voltammetric studies to date have relied on ways of activating the release of these compounds from nerve endings, varicosities and dendrites by using electrical stimulation.[3,6,7,14,16,19,20,22] In addition, chemical stimuli such as *d*-amphetamine, excess potassium, veratridine, and tyramine have been extensively used to cause the release of neurotransmitters.[8,9,59,68–70] Moreover, in freely moving animals, systemically administered drugs and even self-administered drugs have been used to activate release processes.[10,11,49,64–66] An example of the dramatic differences seen between potassium-evoked release of DA and *d*-amphetamine-induced overflow of DA which were recorded from a rat striatal brain slice is seen in Figure 3. These data also demonstrate the power of the temporal resolution afforded by these recording techniques.

6.2 Uptake/Reuptake and Diffusion

The major mechanism for inactivating released neurotransmitters is through membrane-bound proteins known as transporters. These efficient proteins shuttle the released neurotransmitter back into the neuron and inactivate the signal produced by the neurotransmitter.[16,94] Voltammetric methods are ideally suited to studying the function of the DA, NE and 5-HT neuronal transporters.[3–5,7–9,13–16,18,20,55,57] This is carried out using FSCV and HSC in whole animals and brain slices, and RDEV in brain minces or cells. In addition, the diffusional properties of DA, NE and 5-HT in different brain regions can be studied by these methods. This is an emerging area of study, which requires the speed and spatial resolution of the voltammetric methods. An example of the measurement of DA uptake in brain slices of the rat striatum and the effects from cocaine is seen in Figure 4. Interestingly, Wightman and co-workers have developed a model based on electrical stimulation of the slice or intact animal that allows for measurement of both release and uptake parameters in the same preparation.[3,7,14,16,57]

Figure 3 HSC recordings of the effects of potassium-evoked overflow (KCl, ——) and *d*-amphetamine-induced (- - - -) efflux of DA in the rat striatal slice. Potassium and *d*-amphetamine were added to the superfusion bath at time 0 for 2 min. Note the long time course of the *d*-amphetamine-induced release of DA.

Figure 4 HSC recordings of the effects of cocaine (50 µM) on DA uptake in a brain slice from the rat striatum. DA was ejected from a glass micropipette at 5-min intervals. Cocaine was applied during the time period denoted by the black bar above the recording.

7 QUANTIFICATION AND IDENTIFICATION ISSUES

Perhaps the greatest controversy that has surrounded voltammetric measurements in CNS tissues and cells in culture concerns the identity of the detected molecules. Although voltammetric methods are inherently selective compared to many methods because of the relatively few electroactive compounds present in brain tissues and cells coupled with the use of low-oxidation potentials to limit the number of analytes that can be measured (see Table 1), there has always been concern that ''you don't know what you are measuring with the in vivo voltammetric recordings.'' Unlike microdialysis methods that use powerful separation techniques such as HPLC to separate molecules prior to detection, the microelectrodes

can see a number of molecules at the same time. This can confound the interpretation of in vivo voltammetric data. This has prompted the extensive development of electrode coatings (see below) to enhance further the selectivity of the microelectrodes for neurotransmitters or neurochemicals of interest. In fact, the real challenge for future development of microelectrodes is to develop microelectrodes and methods that are specific to a given molecule. In reality, any coating produces a diffusion layer that slows the response time of the microelectrode. This has limited the use of surface-modified electrodes for certain studies, such as rapid single cell recordings. However, electrode surface coatings that can solve some of the specificity problems are still under development.

7.1 Recording Methods

The best tools to use to identify further the detected molecule during fast recordings ($\geq$1 s) have involved the use of FSCV, FCV and the HSC recording methods.[6–12,14–16,19–20,22–24,68–70] As pointed out in section 3, the reduction/oxidation current relationship gives signatures for the detection of DA or 5-HT as compared to interferents such as AA and monoamine metabolites such as 5-HIAA and DOPAC. For example, DA yields distinctive cyclic voltammograms with the rapid voltammetry methods as well as distinctive reduction/oxidation current ratios using HSC recordings.[6–12,19,20,22–25,68–70] This is true for the measurement of 5-HT as well. Confirming the detection of NE versus DA is more difficult.[8,12] These chemical ''signatures'' are reliable measurements because they are fundamental properties of the detected compound.

7.2 Electrode Coatings

Electrode coatings to enhance the selectivity of microelectrodes for certain analytes and to make them sensitive to compounds that are not readily oxidized or reduced is a large area of scientific growth in the area of microelectrode development. In addition, such coatings can protect the surfaces of microelectrodes from fouling. Unfortunately, such layers can decrease the response times of the recordings, due to the diffusion layers created by these surface coatings.

7.2.1 Nafion™

Nafion™ is a Teflon® derivative that has sulfonic acid groups substituted into the polymer matrix. The sulfonate groups are negatively charged and this property has been used extensively to repel anions from electrode surfaces and prevent microelectrodes from fouling. Nafion™ films are one of the most widely used methods for improving the selectivity of voltammetric recordings in CNS tissues.[8,12,14,55,57,59,68–70] As well as repelling anions, Nafion™ is thought to concentrate cations like DA at the electrode surface. Nafion™ is commercially available as suspensions in alcohol (5%, Aldrich Chemical Company). Electrodes are simply dipped into this mixture or Nafion™ is electroplated on to the electrode surface.[55] Many methods of drying have been investigated including air drying,[4,5,18] use of heat guns,[12,14] and oven baking.[68–70] The effect upon electrode sensitivity of the various coating and drying methods can vary between laboratories and experimenters. However, Nafion™ has been consistently used to enhance the selectivity of CFEs or carbon monofilament microelectrodes by $\geq$100 : 1 for DA, NE and 5-HT compared with AA, uric acid, DOPAC and 5-HIAA. The tradeoff with Nafion™ is the thicker the coating, the greater the selectivity for cations versus anions but the slower the response time.

7.2.2 Electropolymerized Coatings

(Poly)phenylenediamine (PPD) has been used as a coating to achieve selectivity and prevent fouling on electrodes. Selectivity is attained due to size exclusion. The electropolymerized coating has holes that allow small molecules like NO and H_2O_2 to diffuse to the electrode surface to be oxidized while blocking larger organic molecules such as DA from the electrode. The *ortho*, *para*, and *meta*-isomers of phenylenediamine have been investigated as well as combinations with catechol and resorcinol.[95] We have developed a microelectrode based on a Nafion™-coated, *o*-phenylenediamine-modified CFE to measure NO selectively. Good selectivity over ascorbate, DA and nitrite has been observed. HSC (resting potential (E_o) = 0, applied potential (E_{max}) = +0.9 V) and amperometry (E = +0.9 V) were used to measure NO selectively.[34,96]

Overoxidized films have been proposed as a substitute for Nafion™ films. When oxidized, polypyrrole is a cationic conducting polymer. When overoxidized, the cationic groups are replaced by carbonyl and carboxylic acid groups. These oxygen-containing groups repel anions such as ascorbate while attracting cations like DA. These electrodes were shown to be more sensitive to DA than Nafion™-coated electrodes with FSCV.[97]

7.2.2 Porphryin

A prophyrinic-based microsensor for measuring NO was introduced by Malinski and Taha. Polymeric porphyrin was electrochemically deposited using CV on to carbon fibers from monomeric nickel tetrakis(3-methoxy-4-hydroxyphenyl)porphyrin (TMHPP). NO showed a peak at +0.63 V while NO_2^- had a peak at +0.8 V. A layer of Nafion™ was used to overcome the nitrate (NO_2^-) interference. DPV and amperometry were used to measure

NO with detection limits of 20 and 10 nM (signal-to-noise ratio = 3), respectively. The tip of certain types of microelectrode can be made small enough to penetrate individual cells.[33] This sensor has been applied to measurements of NO in rat brain[98] and in arteries.[99]

7.2.3 Enzymes

Enzymes can be coated or immobilized on to electrodes to measure analytes that are not electroactive. This is another area of major growth in this field. The analyte is enzymatically converted to an electroactive product, which can be monitored at the electrode surface. Enzymes are often very selective for a particular substrate, which contributes to the selectivity of such enzyme-based sensors.

Oxidase and dehydrogenase enzymes are commonly attached to the surfaces of the microelectrodes. Oxidase enzymes produce hydrogen peroxide as one of their products and the oxidation of hydrogen peroxide is monitored at the electrode. Glucose, lactate, choline, and glutamate oxidase enzymes have been made commercially available. Microelectrodes for all of these molecules have been reported. Because oxygen is consumed in the reaction, microelectrodes built around this scheme sometimes have noticeable oxygen dependence. The second class of enzyme is dehydrogenase enzymes. They oxidize the substrate while reducing NAD^+ (nicotinamide adenine dinucleotide (oxidized form)) to NADH (nicotinamide adenine dinucleotide (reduced form)). Schemes for detecting NADH have been developed. An excess of enzyme is usually immobilized on to the electrode to increase sensor lifetime.

7.2.3.1 L-Glucose Much work has been done to develop sensors to measure L-glucose.[100–106] This research has been motivated by the need to monitor continuously blood glucose levels of people suffering from diabetes. Typically, amperometry with an applied potential between +0.6 and +0.7 V is used to measure peroxide at a platinized carbon,[107] platinum[60,61] or platinum iridium electrode.[35] Using this microelectrode design, glucose has been measured in the rat brain.[40,41,108]

7.2.3.2 Lactate Similarly, lactate oxidase can be used to convert lactate into electroactive peroxide. Enzyme-modified CFEs have been used to measure lactate in the rat brain.[38,39]

7.2.3.3 Choline Peroxide can be measured at a carbon electrode by using horseradish peroxidase and an osmonium poly(vinylpyridine) redox polymer to shift the recording potential to −0.1 V versus SSCE. In this scheme, leaching of enzymes and the redox mediator is minimized. Another advantage is that interferents are minimized due to the low recording potential.[109] A miniaturized version of this sensor was applied to the measurement of local injections of choline in rat brain. Choline oxidase was included in the polymer to sense choline.[110] The detection limit was 1 μm for choline and response times were from 2 to 30 s.

7.2.3.4 L-Glutamate By using dehydrogenase enzymes, detection of NADH or NAD(P)H (nicotinamide adenine dinucleotide phosphate (reduced form)) can be used to track changes in glutamate. However, high overpotentials are required to oxidize NAD(P)H (+1.1 V at carbon[111] and +1.3 V at platinum).[112] High overpotentials are undesirable because of surface fouling, oxidation of interferents present in the sample, and high background currents. The major challenge is to oxidize NADH or NAD(P)H at lower potentials. Electron mediators, which lower the required potential to that of the mediator, have been employed for this purpose. Alvarez-Crespo et al. have described a glutamate sensor based upon a modified carbon paste electrode that was coated with PPD.[112] The nonconductive PPD film not only limits interferents from reaching the electrode and inhibits leaching of soluble species from the electrode surface, but in this case it allowed a lower potential (0 V versus Ag/AgCl reference) to be used for detection of the NAD(P)H produced from the glutamate dehydrogenase enzymatic reaction. An LOD of 3.8 μM was observed. Curulli et al. coated electrodes with 1,2-, 1,3-, 1,4-diaminobenzene (DAB) and 4-aminobiphenyl in the presence of pyrroloquinolinequinone (PQQ) using CV to obtain a layer through which only small molecules can pass to the electrode surface.[113] PQQ acts as an electron mediator for oxidation of NADH. Assembling and evaluation of new dehydrogenase enzyme electrode probes obtained by electropolymerization of aminobenzene isomers and PQQ on gold, platinum and carbon electrodes were examined. The use of the electropolymerized layer increased selectivity. PQQ made the electrodes capable of catalyzing the oxidation of the reduced form of NADH at a potential of +0.2 V. Glutamate dehydrogenase was entrapped in the polymer, which made the electrode sensitive to glutamate with a detection limit of 5 μM.

Enzymes can also be immobilized on to the electrode surface using glutaraldehyde as a cross-linker. Pan and Arnold developed a glutamate sensor consisting of a Pt electrode (diameter = 1.6 mm) coated with Nafion™ followed by glutaraldehyde cross-linked glutamate oxidase.[60] The anionic polymer Nafion™ was used to repel anions such as ascorbate while allowing hydrogen peroxide to be detected at the electrode surface. They reported an LOD of 0.3 μM with linearity up to 800 μM.

Entrapment of the enzyme within a polymer matrix has also been employed.[61] O'Neill et al.[61] have reported a glutamate sensor based on a 60-μm diameter platinum wire electrode that was dip-coated in a glutamate oxidase solution (200 units mL^{-1}, phosphate buffer, pH 7.4). *o*-Phenylenediamine was electropolymerized to entrap the enzyme. This method was an efficient use of enzyme compared to copolymerization.[61]

Enzymes can also be covalently attached to the electrode surface. Avidin was used to attach biotin-modified enzymes to a biotin-modified CFE.[114] In addition, membranes with immobilized enzymes have been attached to larger electrodes.

Elimination of interferents is generally done using coatings of Nafion™,[60] cellulose acetate,[35] and PPD.[61] Enzymes themselves can be used to eliminate interferents. Hu and Wilson et al. developed a glutamate electrode based on a two-enzyme design.[35] Selectivity was obtained by coating the Pt–Ir wire (diameter = 0.17 mm) with the anionic polymers Nafion™ and cellulose acetate and incorporating ascorbate oxidase into the enzyme layer. Ascorbate oxidase removed the interferent AA. Excellent sensitivity and selectivity were reported; however, the two-enzyme design gave the sensor a larger oxygen dependence.

8 COMPARISON WITH OTHER METHODS

8.1 Microdialysis

Microdialysis involves implanting a probe (200–300 μm in diameter by 0.5–4.0 mm in length) which has a dialysis membrane that will allow transfer of compounds of a given molecular weight range. Fluid is pumped through the microdialysis probe at flow rates of 0.3–2.0 μL min^{-1}. The fluid, usually artificial cerebrospinal fluid, is collected at regular intervals (ca. 5–20 min). The compounds of interest that diffuse into the dialyzing fluid are analyzed off-line by HPLC/EC, liquid chromatography with fluorescence detection or gas chromatography combined with mass spectrometry detection. Some people have considered microdialysis methods to be comparable to in vivo voltammetric methods. In reality, these methods are complimentary. In vivo voltammetric methods sample much smaller areas (5–30 μm) at sampling rates of often 1–200 Hz. In addition, the response of a microelectrode is not impeded by the slow exchange of materials that occurs at the microdialysis membrane. Moreover, the microdialysis methods can modify the extracellular space composition. Studies suggest that the microdialysis probe can greatly change the properties of neurons adjacent to the probe.[115] However, typical detection limits for voltammetric recordings of DA and 5-HT with microelectrodes are in the 25–50-nM range. This is poor compared to the routine picomole LODs achieved by analytical methods, such as HPLC/EC, that are used to measure neurotransmitters in microdialysis fractions. Thus, in vivo voltammetric methods have greater spatial and temporal resolution compared to microdialysis, but lack the sensitivity and ability to separate and quantitate numerous compounds that exist simultaneously in the extracellular space of the brain.

8.2 Fiber Optic Sensors

Fiber optic sensors have been used to measure neurotransmitters. Light of a desired wavelength is directed through a single optical fiber or a bundle. The light interacts with the chemical sensing end of the probe that is in contact with the sample. Light that has been modified by the compound of interest is collected with the same or different fibers then measured at a detector. Optical detection has the potential advantage of reduced electrical noise compared to electrochemical detection. In addition, multiple wavelengths can be used to identify compounds selectively. The disadvantage is that they are in general less sensitive than electrochemical detection and the instrumentation involved often precludes their use in freely moving animals. In addition, the sizes of fiber optic probes are too large for recordings of single cells. Fiber optic sensors have been reported for many compounds including NO[116,117] and glutamate.[118–120] To date, voltammetric-based recording methods have been more widely utilized for neurochemical detection than fiber optic sensors.

ABBREVIATIONS AND ACRONYMS

AA	Ascorbic Acid
CA	Chronoamperometry
CFE	Carbon Fiber Electrode
CNS	Central Nervous System
CSCV	Continuous Scan Cyclic Voltammetry

CV	Cyclic Voltammetry
DA	Dopamine
DAB	Diaminobenzene
DHPG	3,4-Dihydroxyphenylglycol
DNPV	Differential Normal Pulse Voltammetry
DOPA	3-(3,4-Dihydroxyphenyl)alanine
DOPAC	3,4-Dihydroxyphenylacetic Acid
DOPEG	Dihydroxyphenylethylene Glycol
DPA	Differential Pulse Amperometry
DPV	Differential Pulse Voltammetry
FCV	Fast Cyclic Voltammetry
FSCV	Fast-scan Cyclic Voltammetry
GABA	γ-Aminobutyric Acid
HPLC/EC	High-performance Liquid Chromatography Coupled to Electrochemical Detection
HSC	High-speed Chronoamperometry
HVA	Homovanillic Acid
ID	Inside Diameter
LOD	Limit of Detection
LSV	Linear Sweep Voltammetry
MAO	Monoamine Oxidase
MHPG	3-Methoxy-4-hydroxyphenylglycol
NAD^+	Nicotinamide Adenine Dinucleotide (Oxidized Form)
NADH	Nicotinamide Adenine Dinucleotide (Reduced Form)
NAD(P)H	Nicotinamide Adenine Dinucleotide Phosphate (Reduced Form)
NE	Norepinephrine
NO	Nitric Oxide
OD	Outside Diameter
PPD	(Poly)phenylenediamine
PQQ	Pyrroloquinolinequinone
RDE	Rotating Disk Electrode
RDEV	Rotating Disk Electrode Voltammetry
SSCE	Sodium Saturated Calomel Electrode
TMHPP	Tetrakis(3-methoxy-4-hydroxyphenyl)porphyrin
3-MT	3-Methoxytyramine
5-HIAA	5-Hydroxyindoleacetic Acid
5-HT	Serotonin
5-HTP	5-Hydroxytryptophan

1 Historical Review 3
2 Analysis 6
Abbreviations and Acronyms 6
References 6

The term ''carbohydrate analysis'' tends to have a different meaning for the different types of carbohydrates. For low-molecular-weight molecules (monosaccharides and simple oligosaccharides) it is generally taken to mean their separation and quantification, whereas for larger molecules and glycans derived from glycoproteins and glycolipids it may involve these factors but it is primarily the determination of the structure that is usually important. There are a number of electronic resources that are available to help clarify the rather specialized language used by the carbohydrate analyst and to provide databases of carbohydrate structures and nuclear magnetic resonance (NMR) spectra (Table 1).

Carbohydrates form a very diverse group of molecules usually made up from basic structures that commonly have a backbone of five or six carbon atoms and possess several alcohol groups and a hemiacetal or, more rarely, a hemiketal group. Less commonly found are carbohydrate units containing a nine-carbon backbone, whereas those with seven and eight carbons are sometimes found in bacteria. There are a number of isomers possible for these structures. As an example, a carbohydrate with six carbon units $(CH_2O)_6$ may be an aldehyde or ketone. The aldehyde form has four chiral centers allowing 16 isomers (2^4), each of which may cyclize to form either five- (furanose) or six (pyranose)-membered rings, which additionally introduces a further chiral center so totaling 64 possible structural entities. The ketone form with one less chiral position may consist of 32 structurally distinct entities. These units (*monosaccharides*) can join together by means of acetal or ketal (*glycosidic*) linkages to form oligomers (*oligosaccharides*) and polymers (*polysaccharides*), both of which may be termed glycans. These linkages can form in a number of ways between the monosaccharide units utilizing any of the hydroxyl groups and forming unbranched and multiply branched structures, such branching being either essentially ordered or disordered. Different monosaccharides may be joined together in an ordered or apparently random manner to form a mainly homogeneous or heterogeneous family of structural entities. These structures may also be linked to proteins and/or lipids as the glycans in glycoproteins, glycosaminoglycans and glycolipids. As these carbohydrates are not directly genetically coded but depend on the sequential action of enzymes, which are only capable of recognizing the local structural arrangement of up to about 12 residues or so, they are commonly found to be heterogeneous. This may be a microheterogeneity, as evident in glycoprotein glycans where most of the structure remains fixed but a variety of structures exist due to missing residues at the molecule's periphery. Alternatively, there may be sequence and linkage heterogeneity as found in heteropolysaccharides or the molecular weight heterogeneity of homopolysaccharides. Polysaccharides are inherently highly polydisperse.

Each natural glycan appears to have one of three main purposes: as a food store; playing a structural role; or as a bearer of information in molecular or cellular recognition. Their structure determines, and will be determined by, their use. Although it is recognized that some simple low-molecular-weight glycans play a structural role as part of glycoproteins where they may alter the secondary, tertiary, and quaternary structure, many structural glycans are relatively stable, of high molecular weight, anisotropic and have a single backbone with little or no complex branching. Food glycans are easily hydrolyzed and have a high proportion of nonreducing termini. Information-bearing glycans often have very complex but specific and relatively low-molecular-weight structures. Carbohydrates play a major part in all living organisms. Understanding the structure of carbohydrates helps our understanding of these biological roles.

The analytical problems surrounding the carbohydrates are clearly orders of magnitude more difficult than that of protein analysis. Indeed, it is apparent that for many polysaccharides no two molecules are likely to be identical and the concept of ''structure'' must be interpreted differently from that for proteins. There is a further level of complexity if the conformation of the carbohydrates in solution is sought because, in contrast to protein structures, these are generally not fixed but fluctuate widely and may change irreversibly during isolation or with changes in the temperature, solvent, pH, ionic strength, concentration or co-solutes.

Fortunately, although the analytical task remains formidable, the full range of monosaccharide, ring size and linkage diversity is not found, with most glycans being constructed out of a very limited subset of possible molecular building blocks (Figure 1). For example, not counting equilibrium structures, there are 30 different D-glucose dimers and 1120 different D-glucose trimers possible

Structures **(17)**, **(18)**, **(25)** and **(28)** are furanoses, the rest being pyranoses. Structures **(1–6)**, **(25)**, **(27)** and **(28)** are hexoses, **(7)** is an aminohexose, **(8–10)** are *N*-acetamidohexoses, **(11)**, **(12)** and **(22)** are deoxyhexoses, **(13–16)**, **(21)**, **(32)** and **(33)** are hexuronic acids and **(17–20)** and **(30)** are pentoses. Structures **(2)**, **(4–6)**, **(8)**, **(10)**, **(11)**, **(14)**, **(15)**, **(17)**, **(20)**, **(22)** and **(29)** are relatively common, whereas **(7)**, **(12)**, **(16)**, **(18)**, **(23)**, **(24)**, **(26–28)** and **(30–33)** are found only rarely, the remainder occurring occasionally. Other monosaccharide residues (not shown) are found very rarely, with microorganisms in particular producing a wide variety of rare monosaccharide units. Compounds are also found as derivatives with some or all of sulfate, phosphate or acetyl groups or as their methyl ethers.

Figure 1 (*Continued*)

but only six dimers and three trimers are commonly encountered (maltose, cellobiose, isomaltose, gentiobiose, α,α-trehalose, sophorose, cellotriose, maltotriose and panose). However, the analysis of polysaccharides and glycans remains challenging and must be tackled in a systematic manner.

1 HISTORICAL REVIEW

It is surprising that carbohydrates, given the present difficulties in their structural analysis, were amongst the first natural products to be isolated, quantified and to have their structures determined. The straightforward, if flawed, analysis of mixtures of glucose, fructose and sucrose, using the rotation of polarized light, facilitated the early studies on enzyme kinetics. This determination was used by Berthelot[1] in 1860 in the first proof of the catalysis of biological reactions by nitrogenous material (enzymes), by Sørenson[2] to show the effect of pH on enzyme (invertase) activity in 1909 and by Michaelis and Menten[3] in 1913 to underpin the early development of enzyme kinetics. The determination of specific rotation is still used as a confirmatory technique and in those rare instances where mixtures of both anomeric forms of component sugars are present in complex glycans and their ratio is required.

Before powerful chromatographic methods evolved, a number of colorimetric assays were developed involving the reducing power of the low-molecular-weight sugars or by coupling to suitable molecules such as phenol after acidic dehydration.[4] Some of these assays were developed further to give different responses with different monosaccharides. They remain of considerable use to this day, particularly where just the concentration of a known carbohydrate is required. Where selectivity is required, these assays are replaced by colorimetric or fluorimetric assays involving enzymatic conversions.

Early analytical work in the 1940s and 1950s centered on the use of paper chromatography to separate the component sugars from acid-hydrolyzed polysaccharides, with much effort being applied to the selection of the developing solvents and the detection methodology. Although paper chromatography is easy and inexpensive, can separate a wide variety of structural types, including oligosaccharides and some polysaccharides, without their prior derivatization and generally ensures that no components go undetected, it is only rarely used nowadays. In the 1960s and 1970s, paper chromatography was developed into thin-layer chromatography with its greater resolving power, and in the 1980s to high-performance thin-layer chromatography. These improved methodologies possess very much greater resolving power and improved quantification but are little used in modern carbohydrate analysis, apart from their important utility for separating glycolipids, having been generally outclassed by high-performance liquid chromatography (HPLC) techniques.

Another development from paper chromatography was the use of column chromatography. Initially these consisted of charcoal or cellulose, and then the ion exchange and ion exclusion matrices that have evolved over the years into the high-performance columns used today. Although these separation techniques generally work well, a major problem has been in the detection of carbohydrates. Unlike proteins, carbohydrates have no natural ultraviolet absorption, color or fluorescence. Free aldehyde or ketone groups do absorb ultraviolet light but only below about 200 nm, and then rather inefficiently. This does allow their detection but only when noninterfering eluents, such as pure water or acetonitrile, are used. Refractive index detectors have been commonly used but these are rather insensitive and easily confused by changes in eluent composition such as solute gradients. Many pre- and post-column derivatization processes have been devised in order to facilitate sensitive spectrophotometric determination. Relatively recently, the introduction of pulsed amperometric detection has driven forward the use of HPLC for carbohydrate analysis. This methodology in which about 1% of carbohydrate alcohol groups are oxidized at a gold electrode when in alkaline solution, has proved to be both sensitive and reliable. In this system the gold electrode is utilized and cleaned about once every 1 s by a series of oxidative and reductive electrical pulses. This methodology has been coupled to the development of alkali-stable anion exchange resins for use in high-performance anion exchange chromatography (HPAEC).

Improved separation techniques are constantly being developed with very high resolutions and capable of distinguishing even quite closely related glycans. When coupled to detection by mass spectrometry (MS), they can form a powerful part of the carbohydrate analytical toolbox.

Gas chromatographic methods were commonly used for the analysis of monosaccharides in the 1960s, when their high sensitivity and resolution placed them well ahead of the, then current, liquid chromatographic methods. Their development depended on methodology, based on trimethylsilylation or the acetylation of their alditols, to convert the inherently involatile carbohydrates into volatile derivatives. Although currently often replaced by HPAEC, gas chromatography methods are still used because the technique is well understood. Gas chromatography is particularly useful for the analysis of partially methylated alditol acetates produced by methylation analysis and where coupled MS is necessary.

The absolute configuration (D or L) of monosaccharides was an important part of early analyses, involving a considerable degree of effort and ingenuity. This was achieved via the relatively large-scale purification of hydrolysis-derived monosaccharides, followed by their chemical characterization. Where possible, the configuration was decided or confirmed by X-ray crystallography. Once sufficient absolute structures had been established, materials were determined by comparison of their specific optical rotation. Much simpler chiral chromatographic methods now exist, but absolute configurations are only rarely specifically established, because most work is on materials where this is already known or may be assumed from, for example, the use of enzymes of known specificity.

Linkage analysis was first determined, in the 1940s, by means of the analysis of fragments produced by periodate. This method, which depends on the ability of periodate to cleave between neighboring unlinked alcohol groups, is still used occasionally to help solve otherwise intransigent problems. A useful development of the technique is the Smith degradation,[5] where (nowadays) borohydride reduction of the resultant aldehydes and chromatography of the resultant alcohols follow oxidation. The introduction of a powerful and efficient methylation procedure by Hakomori[6] in 1964 allowed linkage positions to be determined more explicitly, and developments of this methodology, coupled with the use of gas chromatography/mass spectrometry (GC/MS), are commonly used today. Linkage analysis normally must be combined with other techniques such as partial hydrolysis and NMR if more than localized structural arrangements are to be determined.

Determination of the anomeric configuration has always been achieved by the use of specific enzymes. The use of enzymes also confirms the absolute configurations. Sequence analysis has always been problematic. Glycoprotein glycans, where the monosaccharide units are linked together in precise and generally well-understood sequences, can be investigated successfully by the controlled and sequential addition of specific

exoglycosidases. Advances over the years have concerned the range of available enzymes and the more detailed knowledge concerning their specificity. Although suitable enzymes are often not easily available, this is an important area of research and there is likely to be considerable progress in the future. Recently, NMR has been used to distinguish the anomeric configurations and sequence of oligosaccharides in many cases.

The determination of the molecular weight of carbohydrate-containing polymers has been decidedly difficult until recently. This is because they may be very large, they hold on to large amounts of water, they may possess very anisotropic structures and there are few ''standard'' molecules with known structures that are suitable for comparison with the unknown substances. Analytical ultracentrifugation was commonly used in the 1940s and 1950s but is rarely used nowadays. Size exclusion chromatography has proved to be very useful in determining the size of proteins but is of limited use for large carbohydrates, except as a means of separation, owing to the very different ways in which carbohydrate-containing molecules behave in solution and the typical inapplicability of the available calibration molecules. Although light scattering was one of the earliest methods available, in the 1940s, for determining molecular weights in solution, it is only the recent introduction of multi-angle laser light scattering (MALLS) that has made this technique widely accepted. MALLS allows the relatively straightforward and accurate determination of the absolute weight-averaged molecular weight (M_w) of large carbohydrate-containing molecules without the need for standards. In its most powerful mode it can be used as part of HPLC detection to monitor continuously the molecular weights and shapes of the materials eluted. Number-averaged molecular weights (M_n) and polydispersity (M_w/M_n: a measure of the breadth of the molecular weight distribution) can also be estimated by this method.

Although NMR has been used for many years, the one-dimensional spectrum of most carbohydrates is generally too complex to be assigned fully. There remain, however, sufficient ''reporter'' groups for much useful information to be obtained. In particular, the monosaccharides present, their anomeric conformations and ring size (i.e. pyranose or furanose) and some indication of the linkages present are usually determinable. With the development of multidimensional techniques and powerful (600-MHz) instrumentation, NMR is proving to be a dominant technique for determining complex protein structures but has not yet had a similar level of success with large carbohydrates. The spectra for medium or large molecules are extremely complex and difficult to interpret but NMR has proved valuable for determining or confirming the structure of oligosaccharide fragments, and a database of structural assignments is being built up. NMR is capable of determining the sequence, linkage position and anomeric configuration. Although it is, potentially, a most powerful method for determining the conformation of carbohydrates, this use of NMR is still in its infancy with respect to glycans. A major drawback for the technique is its lack of sensitivity, particularly as many polysaccharides have limited solubility, form gels or are relatively inflexible in solution. Often such molecules give rise to poor spectra owing to their unfavorable relaxation properties.

The specific binding of antibodies or lectins to carbohydrates has been used to show the existence and availability of particular substructures within complex carbohydrates and may be used in carbohydrate separation and purification. As the family of known lectins has grown over the years and their characterization has improved, they have become useful tools for distinguishing between closely related glycans without the need for full analyses.

MS can be used to determine the molecular weight of low- and medium-molecular-weight carbohydrates of up to about 10 kDa. For some molecules, tandem mass spectrometry (MS/MS) can also give compositional, sequence and linkage information. Little success has been reported for higher molecular weight polysaccharides, perhaps due to the inherent heterogeneity of carbohydrate samples. The main restriction with MS is that isomeric monosaccharides, such as glucose and galactose, cannot be distinguished. The technique can be very sensitive, with only subpicomole amounts being required. Electrospray ionization MS may be used as a detection system for HPLC, capillary electrophoresis and capillary isoelectric focusing. Such systems are very powerful in that they can achieve two-dimensional separations based on MS and chromatography.

The area of conformational analysis remains one of the most intransigent problems in carbohydrate analysis. This is partly because of the vast number of possible local conformational potential energy minima possible: for just four 1→4-linked hexopyranoses joined together, there are about 3^{25} (approximately 1 trillion) possible local potential energy minima. For medium and large glycans the number of local minima is so vast that it is possible for only a fraction of the conformations to be sampled during their existence. In addition, a significant number of these conformations are in deep potential energy wells. Most sizeable molecules will therefore consist of mixtures, with little chance that any two molecules are conformationally identical unless they possess long-range order such as the presence of helices. NMR is capable of determining the conformation of these carbohydrates but will deliver time-averaged conformations that may or may not be true reflections of the actual conformations. In such circumstances, although there may be little meaning to any one ''averaged'' conformation, knowledge concerning the typical conformational motifs can be a very useful

aid in discussing the glycan's molecular interactions and functional properties. Additionally, where multiple conformational states exist and are in rapid equilibrium (i.e. usually), the lack of unique torsional angles and time averaging of the NMR data combine to blur the conclusions that can be drawn. Molecular modeling is helping for making inroads into solving this conformation problem. Its present restricted usefulness, due to the vast memory and computational requirements, is being rapidly overcome.

2 ANALYSIS

No single method suffices for the analysis of glycans, in contrast to protein analysis where either X-ray crystallography or NMR may be sufficient. In addition, crystalline protein structures appear to be very similar to their structure in solution, whereas carbohydrates that take up very different conformations with no clearly defined structure in solution may form a regular structure in the solid state. Isolation and purification are also more likely to affect the structure and conformation of high-molecular-weight carbohydrates than proteins. The structural determination of most complex carbohydrates utilizes a wide variety of methodologies, often including the use of enzymes, methylation analysis, MS and NMR; these methods complement and reinforce each other. A complete structural determination of an unknown glycan, subsequent to its isolation and purification, involves the following stages, which are often undertaken approximately in the order given:

- determination of the constituent monosaccharides, their absolute configuration (D or L), their ring size and any derivatization they have undergone, such as sulfation, methylation or acetylation;
- determination of the molecular size or molecular size distribution;
- determination of the anomeric configuration of the linkages (α or β);
- determination of the linkage positions between the monosaccharide units;
- determination of their sequence, including any repetitive pattern in the structure and the degree of any heterogeneity;
- determination of any preferred conformation of parts or all of the molecule(s) present.

The more important analytical methods appropriate to different carbohydrates are given in Table 2. A modern carbohydrate analytical facility clearly involves the availability of a range of expensive instrumentation and staff skilled in a variety of chemical and biochemical techniques.

Table 2 Major analytical methods for carbohydrates

Monosaccharides	Colorimetric assays, GC/MS, HPAEC
Oligosaccharides	HPAEC, high-performance thin-layer chromatography, methylation analysis,[a] MS, NMR
Polysaccharides	Enzymatic cleavage,[a] methylation analysis, size exclusion chromatography plus MALLS
Glycolipids	HPLC, high-performance thin-layer chromatography, methylation analysis, MS, NMR
Glycoprotein glycans	Capillary electrophoresis, enzymatic cleavage, HPLC, methylation analysis, MS, NMR, use of lectins
Glycosaminoglycans	Capillary electrophoresis, enzymatic cleavage, extractive methods

[a] Methods involving cleavage produce monosaccharides and/or oligosaccharides.

This section of the Encyclopedia (i.e. carbohydrate analysis) has articles on all the main classes of carbohydrates selected on the basis of class rather than methodology. Each class (**Monosaccharides and Sugar Alcohol Analysis; Disaccharide, Oligosaccharide and Polysaccharide Analysis; Proteoglycan and Acidic Polysaccharide Analysis; Glycoprotein Analysis: Using Nuclear Magnetic Resonance; Glycoprotein Analysis: General Methods** and **Glycolipid Analysis**) has its own particular analytical direction, although all involve analysis of their component monosaccharides. They may use related methodology for part of their analytical schemes but they also use their own characteristic methods based on their distinct structures and properties.

ABBREVIATIONS AND ACRONYMS

GC/MS	Gas Chromatography/Mass Spectrometry
HPAEC	High-performance Anion Exchange Chromatography
HPLC	High-performance Liquid Chromatography
MALLS	Multi-angle Laser Light Scattering
MS	Mass Spectrometry
MS/MS	Tandem Mass Spectrometry
NMR	Nuclear Magnetic Resonance

Disaccharides, oligosaccharides and polysaccharides form a very diverse and complex family of biologically important macromolecules. In order to discover their structure it is necessary to determine not only monosaccharides present and their linkage positions and sequence, but also the anomeric configuration of linkages, the ring size (furanose or pyranose), the absolute configuration (D or L) and identify any other substituents present. There is no one method that can be used to determine their fine structure; instead we must use a combination of analytical methods to gain as much information as we can. For analysis of disaccharide and oligosaccharide mixtures, separation and quantification techniques such as colorimetric and enzymatic assays, thin-layer chromatography (TLC) or high-performance anion-exchange chromatography may be applied. For polysaccharide analysis separation and extraction techniques, component analysis, methylation analysis, glycosidic hydrolysis, mass spectrometry (MS) methods, and nuclear magnetic resonance (NMR) spectroscopy are required to determine the fine structure and size exclusion chromatography (SEC) coupled with light scattering (LS) detectors to determine the molecular size distribution.

1 INTRODUCTION

Disaccharides are compounds in which two monosaccharide units are joined by glycosidic linkages. Oligosaccharides are broadly defined as carbohydrate polymers containing up to twenty residues. According to the number of units, they are called trisaccharides, tetrasaccharides, pentasaccharides etc. where the number of units is the degree of polymerization (DP, e.g. tetrasaccharides have a DP of 4). The borderline between oligosaccharides and polysaccharides is not precise, however, and oligosaccharides are generally molecules with precisely defined structures whereas polysaccharides have inexactly defined length or structure.

Polysaccharides form a diverse and complex family of biological macromolecules. The source and structure of some commonly occurring polysaccharides are given in Table 1. They are essentially condensation polymers of monosaccharide units joined by glycosidic linkages. Polysaccharides may be composed of a single sugar unit (termed *homopolymers*) or may contain two or more constituent monosaccharides (*heteropolymers*) joined in a variety of ways. The polymers may be linear, branched or even cyclic in nature and this has important consequences for their physicochemical nature. Polysaccharides are abundant in nature and found in nearly every living organism. They can function as storage polysaccharides, such as starch in plants and glycogen in animals, structural elements in the cell walls of bacteria and plants and skeletal elements in arthropods. They can also be found linked to proteins and lipids, and have been implicated in cell–cell recognition and molecular targeting. Glycoproteins and glycolipids will not be reviewed here as they are discussed in separate articles.

Polysaccharides occurring in nature often have high molecular weights, frequently well in excess of 1000 kDa. They are usually polydisperse in nature and may contain a wide range of closely related structures. The generic term for all polysaccharides is *glycans*. They are often individually classified by adding '*an*' to the end of the constituent prefix for the parent sugar, for example *glucans* for polymers of glucose, *xylans* for polymers of xylose and so on. However many common unsystematic names, such as cellulose, pectin, amylose and inulin, are still in use alongside the systematic ones. Heteropolymers are commonly classified

Table 1 Source and structure of some important polysaccharides

Main sources	Polysaccharide	Polymer structure
Land plants	Arabinoxylan	β-(1 → 4)-linked D-xylose with α-L-(1 → 2), (1 → 3) or (1 → 2)(1 → 3)-linked L-arabinose
	Cellulose	β-(1 → 4)-linked D-glucan
	Galactomannan	α or β linked D-mannan substituted with α or β linked D-galactose
	Glucomannan	β-(1 → 4)-linked D-mannose with β-(1 → 4)-linked D-glucose
	Guar gum	α-(1 → 4)-linked D-galactomannan
	Gum arabic	L-Arabino-, α-(1 → 3)- and α-(1 → 6)-D-galactan with glucuronic acid side chains
	Inulin	β-(2 → 1)-linked D-fructans
	Pectin	Linear and branched α-(1 → 4)-linked galacturonan
	Starch	α-(1 → 4)-linked D-glucose either linear (amylose) or branched (amylopectin) with α-(1 → 6)-linked D-glucose
	Xylan	β-(1 → 4)-linked D-xylose often with substituent groups attached
Marine plants	Agar	Sulfated DL-galactans, contains 3,6-anhydrogalactose units
	Alginates	Linear β-(1 → 4)-D-mannuronan and α-L-guluronan
	Carrageenan	Sulfated β-(1 → 3), α-(1 → 4)-D-galactans
	Laminaran	β-(1 → 3)-linked D-glucan
Micro-organisms	Curdlan	β-(1 → 3)-linked D-glucan
	Dextran	α-(1 → 6), (1 → 3)-linked D-glucan, and sometimes α-(1 → 2) and α-(1 → 4) links
	Levan	β-(2 → 6), (2 → 1)-linked D-fructan
	Mannan	α-(1 → 2), α-(1 → 6)-linked D-mannans, sometimes α-(1 → 3) links
	Nigeran	α-(1 → 3), (1 → 4)-linked D-glucan
	Pullulan	α-(1 → 4), (1 → 6)-linked D-glucan
	Xanthan gum	β-(1 → 4)-linked D-glucan with mannose and glucuronic acid side chains
Animals	Chitin	β-(1 → 4)-linked *N*-D-acetylglucosamine
	Glycogen	α-(1 → 4)-linked D-glucose with some α-(1 → 6)-linked branch points

by placing the branched or lowest unit first and the parent backbone sugar last; for example, rhamnogalactans are polymers with a galactose backbone and rhamnose side-chains.

Polysaccharides can be classified in terms of their monosaccharide composition, type of glycosidic linkages present, sequence of units along the backbone, the relative degree and spacing of the substituted groups along the chain and the DP. Many of the structure–function relationships of carbohydrates have been poorly elucidated due to the difficulty in extraction, purification and fine structure characterization of these complex polymers. However the availability of highly specific glycosidases to break down the polysaccharides backbone and recent advances in techniques such as high-performance liquid chromatography (HPLC), MS and NMR spectroscopy, have enabled a number of fine structures to be elucidated. It is hoped that detailed characterization of these molecules will lead to a greater understanding of their biological role.

Disaccharides and oligosaccharides form a varied class of hydrophilic low-molecular-weight molecules (Table 2). A number of these are nonreducing sugars used as mobile stores to provide for the synthetic needs of their source organism without risk of nonspecific reactions otherwise associated with free reducing termini. Others are mainly found as the hydrolytic products of polysaccharides and other glycans.

In order to discover the structure of glycans, it is necessary to determine not only the monosaccharides present, their linkage positions and sequence, but also the anomeric configuration of linkages, the ring size (furanose or pyranose), the absolute configuration (D or L) and to identify any other substituents present. There is no one method that can be used to determine the fine structure of polysaccharides; instead we must use a combination of analytical methods to gain as much information as we can. For analysis of disaccharide and oligosaccharide mixtures, separation and quantification techniques such as colorimetric and enzymatic assays (section 4), TLC, section 5.1.1) or HPLC, (section 5.1.2) may be applied. For polysaccharide analysis separation and extraction techniques (section 2), component analysis (section 3), methylation analysis (section 5.2), glycosidic hydrolysis (section 5.3), MS methods (section 7.1) and ^{1}H and ^{13}C NMR spectroscopy (section 7.2) are required to determine the fine structure and SEC (section 6.1) coupled with LS (section 6.2) to determine the molecular size distribution.

Table 2 The more commonly encountered disaccharides, trisaccharides and oligosaccharides

Common name	CAS number	Structure
Ajugose		α-D-Gal*p*-(1 → 6)-[α-D-Gal*p*-(1 → 6)]$_3$-α-D-Glc*p*-(1 ↔ 2)-β-D-Fru*f*
Cellobiose	528-50-7	β-D-Glc*p*-(1 → 4)-D-Glc
Cellotriose	6817-81-8	β-D-Glc*p*-(1 → 4)-β-D-Glc*p*-(1 → 4)-D-Glc
Chacotriose	550-72-1	α-L-Rha*p*-(1 → 2)-[α-L-Rha*p*-(1 → 4)]-D-Glc
Chitobiose	577-76-4	β-D-Glc*pN*Ac-(1 → 4)-D-Glc*N*Ac
α-Cyclodextrin[a]	10016-20-3	→ 4)-[α-D-Glc*p*]$_6$-(1–
β-Cyclodextrin[b]	7585-39-9	→ 4)-[α-D-Glc*p*]$_7$-(1–
γ-Cyclodextrin[c]	17465-86-0	→ 4)-[α-D-Glc*p*]$_8$-(1–
Galactosucrose		β-D-Fru*f*-(2 ↔ 1)-α-D-Gal*p*
Gentianose		β-D-Glc*p*-(1 → 6)-α-D-Glc*p*-(1 ↔ 2)-β-D-Fru*f*
Gentiobiose	554-91-6	β-D-Glc*p*-(1 → 6)-D-Glc
Isokestose[d]	470-69-9	β-D-Fru*f*-(2 → 1)-β-D-Fru*f*-(2 ↔ 1)-α-D-Glc*p*
Isomaltose	499-40-1	α-D-Glc*p*-(1 → 6)-D-Glc
Isomaltotriose	3371-50-4	α-D-Glc*p*-(1 → 6)-α-D-Glc*p*-(1 → 6)-D-Glc
Isopanose		α-D-Glc*p*-(1 → 4)-[α-D-Glc*p*-(1 → 6)]-D-Glc
Isotrehalose[e]		β-D-Glc*p*-(1 ↔ 1)-β-D-Glc*p*
Kestose[f]	562-68-5	β-D-Fru*f*-(2 → 6)-β-D-Fru*f*-(2 ↔ 1)-α-D-Glc*p*
Kojibiose		α-D-Glc*p*-(1 → 2)-D-Glc
Lactose	63-42-3	β-D-Gal*p*-(1 → 4)-D-Glc
Lactulose	4618-18-2	β-D-Gal*p*-(1 → 4)-D-Fru
Laminaribiose	34980-39-7	β-D-Glc*p*-(1 → 3)-D-Glc
Laminaritriose		β-D-Glc*p*-(1 → 3)-β-D-Glc*p*-(1 → 3)-D-Glc
Maltose	69-79-4	α-D-Glc*p*-(1 → 4)-D-Glc
Maltotriose	1109-28-0	α-D-Glc*p*-(1 → 4)-α-D-Glc*p*-(1 → 4)-D-Glc
Maltulose		α-D-Glc*p*-(1 → 4)-D-Fru
Manninotriose	13382-86-0	α-D-Gal*p*-(1 → 6)-α-D-Gal*p*-(1 → 6)-D-Glc
Melezitose	597-12-6	α-D-Glc*p*-(1 → 3)-β-D-Fru*f*-(2 ↔ 1)-α-D-Glc*p*
Melibiose	585-99-9	α-D-Gal*p*-(1 → 6)-D-Glc
N-Acetyllactosamine	32181-59-2	β-D-Gal*p*-(1 → 4)-D-Glc*N*Ac
Neokestose	3688-75-3	β-D-Fru*f*-(2 → 6)-α-D-Glc*p*-(1 ↔ 2)-β-D-Fru*f*
Nigerose	34980-39-7	α-D-Glc*p*-(1 → 3)-D-Glc
Nystose	13133-07-8	β-D-Fru*f*-(2 → 1)-β-D-Fru*f*-(2 → 1)-β-D-Fru*f*-(2 ↔ 1)-α-D-Glc*p*
Palatinose		α-D-Glc*p*-(1 → 6)-D-Fru
Panose	33401-87-5	α-D-Glc*p*-(1 → 6)-α-D-Glc*p*-(1 → 4)-D-Glc
Planteobiose		α-D-Gal*p*-(1 → 6)-D-Fru
Planteose		α-D-Gal*p*-(1 → 6)-β-D-Fru*f*-(2 ↔ 1)-α-D-Glc*p*
Primaverose		β-D-Xyl*p*-(1 → 6)-D-Glc
Raffinose	512-69-6	α-D-Gal*p*-(1 → 6)-α-D-Glc*p*-(1 ↔ 2)-β-D-Fru*f*
Rutinose	90-74-4	α-L-Rha*p*-(1 → 6)-D-Glc
Solatriose	528-40-5	α-L-Rha*p*-(1 → 2)-[β-D-Glc*p*-(1 → 3)]-D-Gal
Sophorose	534-46-3	β-D-Glc*p*-(1 → 2)-D-Glc
Stachyose	470-55-3	α-D-Gal*p*-(1 → 6)-α-D-Gal*p*-(1 → 6)-α-D-Glc*p*-(1 ↔ 2)-β-D-Fru*f*
Sucrose	57-50-1	β-D-Fru*f*-(2 ↔ 1)-α-D-Glc*p*
α,α-Trehalose	99-20-7	α-D-Glc*p*-(1 ↔ 1)-α-D-Glc*p*
Turanose	547-25-1	α-D-Glc*p*-(1 → 3)-D-Fru
Umbelliferose		α-D-Gal*p*-(1 → 2)-α-D-Gal*p*-(1 ↔ 2)-β-D-Fru*f*
Verbascose	546-62-3	α-D-Gal*p*-(1 → 6)-[α-D-Gal*p*-(1 → 6)]$_2$-α-D-Glc*p*-(1 ↔ 2)-β-D-Fru*f*

[a] α-cyclomaltohexaose.
[b] β-cyclomaltoheptaose.
[c] γ-cyclomaltooctaose.
[d] 1-kestose.
[e] β,β-trehalose.
[f] 6-kestose.

2 EXTRACTION

The first step in structural polysaccharide analysis is the extraction and separation of a single polysaccharide species from extraneous components. Polysaccharide material must be separated from low-molecular-weight material such as inorganic salts and fat and from other high-molecular-weight material commonly found associated with polysaccharides such as protein. Unless the level of these extraneous components is already known in the sample material, then these must be determined prior to extraction. The key stage is the selective extraction of the appropriate polysaccharide in as high a yield as possible, with minimum effect on the polysaccharide fine structure. The amount of carbohydrate present at each stage of the purification procedure can be monitored using a non-specific carbohydrate assay such as the phenol–sulfuric assay.[1]

Water-extractable polysaccharides can be solubilized in aqueous solutions, and low-molecular-weight material removed by dialysis, ultrafiltration or treatment with ion exchange resins. Other carbohydrate components may be selectively degraded at this stage using the appropriate glycosidase e.g. starch can be removed by enzymatic degradation with α-amylases. The enzymes used must not cause degradation of the polysaccharide of interest. Polysaccharide material can then be isolated from aqueous solutions by graduated fractionation with, for example, ammonium sulfate or ethanol or by lyophilization.

Water-unextractable polysaccharide material can often be solubilized in alkali. If required, extraneous components can be removed prior to alkaline extraction e.g. fat can be solubilized in an appropriate solvent such as chloroform–methanol (95 : 5 v/v) using Soxhlet apparatus and protein can be denatured by suspension in aqueous sodium dodecylsulfate. The extraction step must be carefully designed to minimize base-catalyzed hydrolysis, β-elimination and Lobry de Bruyn–Eckenstein transformations (degrading the reducing end of the molecule), which may otherwise occur under alkaline conditions. It is useful to use an extractant, if possible, which will preferentially select for the carbohydrate of interest. This will simplify the purification procedure. An example is the use of saturated barium hydroxide solution, containing a critical concentration of sodium borohydride, to selectively extract insoluble arabinoxylans from wheat cell wall material.[2] If a sufficiently selective extractant cannot be found, then it may be necessary to introduce further purification steps, such as separation on ion-exchange resins e.g. diethylaminoethyl (DEAE)-cellulose, in order to separate polysaccharide species or provide a sample of sufficient homogeneity for analysis.

3 COMPONENT ANALYSIS

There are many different stereoisomers of hexoses or pentoses that are possible but fortunately for the analyst only a few are commonly found in polysaccharides. These are listed in Table 3. Analysis of the monosaccharide composition of carbohydrates requires complete hydrolysis of all the glycosidic linkages present in the sample. Polysaccharides containing furanoside units such as fructans and arabinans can be completely and rapidly hydrolyzed by treatment with mild acid. Polysaccharides containing pentose sugars as pyranoside units and even more so those containing hexopyranoside units are rather more resistant to hydrolysis. They are still relatively easily hydrolyzed using e.g. 2 M HCl for a period of 2–5 h at 100 °C. If the polysaccharide material is not water-soluble, it may be pre-treated with 72% sulfuric acid for a short period at low temperature to facilitate solubilization followed by dilution and hydrolysis as above. Some residues involved in very acid-resistant glycosidic linkages may not be released by mild acid hydrolysis and may require more stringent techniques. For example uronic-acid-containing polysaccharides, particularly with the aldobiuronic acid type of linkage, require combined treatment of methanolysis (2 M HCl in methanol) followed by hydrolysis with trifluoroacetic acid to release all the components present.[3] The glycosidic linkages of aminosugar residues are also very resistant to acid hydrolysis. In general α-glycosidic bonds are more acid-labile than β-glycosidic bonds.

Analysis of the released monosaccharide components can be identified, after any appropriate derivatization, by a number of chromatographic techniques including TLC, gas chromatography (GC) or HPLC. Driven by improvements, particularly in the type and sensitivity of detectors available, the method of choice for analyzing component sugar composition is probably high-performance anion-exchange chromatography coupled with pulsed amperometric detection (HPAEC/PAD).[4] Column chromatography of the monosaccharides and their derivatives are discussed in

Table 3 Some common sugars occurring in polysaccharides

Type	Monosaccharide
Pentoses	L-Arabinose, D-xylose
Hexoses	D-Galactose, D-glucose, D-mannose, D-fructose, L-galactose
6-Deoxyhexoses	L-Rhamnose
Hexuronic acids	D-Glucuronic acid, D-galacturonic acid, 4-*O*-methyl-D-glucuronic acid
Hexosamines	*N*-Acetyl-D-glucosamine, *N*-acetyl-D-galactosamine

4 ENZYME AND COLORIMETRIC ASSAYS

There are a number of rapid and convenient colorimetric assays available for determination of carbohydrate groups in intact molecules. These tend to be based either on determination of the number of reducing end groups, or on the creation of a chromophore by complexation with the sugar under acidic dehydrating conditions. General carbohydrate assays such as the phenol–sulfuric acid assay are often used to monitor the carbohydrate content of column effluents to give a quick and quantitative measure of, for example, free and combined glucose.[1] Calibration with appropriate standards is necessary, as different sugars will give varying color responses with this assay. More specific assays can be used to detect the presence of particular kinds of sugar such as hexoses, pentoses, uronic acids or aminosugars. For example, pentose can be measured with a modified version of the L-cysteine–sulfuric acid assay,[5] uronic acids using a modification of the carbazole assay[6] and hexoses by any of the general carbohydrate assays. For reducing sugars either the Nelson–Somogyi method[7] or the more convenient dinitrosalicylic acid assay can be used.[8] As with many of the less specific colorimetric assays the reducing sugar assays do not differentiate between sugars and can give varying color responses. Accurate quantitative determination of mixtures of monosaccharides or hydrolyzed polymer structures may be better determined using the more powerful column chromatography techniques such as HPLC.

There are a number of specific colorimetric enzymatic assays available for the determination of individual carbohydrate groups. These are ideal for a quantitative analysis of known carbohydrates in, for example, complex mixtures of food samples. There are a large number of enzymes available for oligosaccharide and polysaccharide analysis, a full summary of which is given in section 5.4. For example determination of starch or sucrose may be achieved by enzymatic hydrolysis to monosaccharides with glucoamylase or invertase respectively, followed by enzymatic determination of glucose using the hexokinase/dehydrogenase assay.[9] There are commercially available kits for the enzymatic detection of sucrose, maltose, lactose, and starch. There are also an increasing number of commercial biosensors available not just for glucose analysis[10] but also for other carbohydrates such as maltose, sucrose and starch for which suitable enzyme systems exist.[11] These are particularly useful for monitoring the effluent in on-line automated HPLC processes.

5 BIOCHEMICAL METHODS OF ANALYSIS

5.1 Separation Methods

5.1.1 Thin-layer Chromatography

TLC can be used as a convenient and semi-quantitative method of analyzing the oligosaccharide hydrolysates of polysaccharides. It can provide a rapid preliminary screening of mixtures of monosaccharides and oligosaccharides giving an indication of the component sugars present and of their relative amounts. This gives valuable information about the composition of the native polysaccharide. Due to the sensitivity of the procedure, even minor components can be detected. Carbohydrates have been separated using a number of different solid supports and an array of solvent systems,[12,13] but no single method is universal and trial-and-error must sometimes be adopted to find appropriate separation conditions. Thin-layer plates can be prepared in the laboratory but, for reproducibility, are best purchased pre-coated with microcrystalline cellulose or silica gel as the solid support. Sugars are separated essentially by liquid–liquid partition, with some element of adsorption in the case of silica gel. Impregnation of silica gel with inorganic salts has been shown to improve resolution with sugar separations. For more complex mixtures of sugars where the R_f values are small, resolution can be improved by performing multiple ascents where the chromatogram is eluted, dried and re-eluted using the same eluent a number of times.

The relative movement of the carbohydrate (R_f) and the efficiency of separation may be affected by laboratory conditions such as humidity, temperature and chromatographic tank size. Variations in the coating batch and coating method may also adversely affect R_f values. Hence, the R_f values for standards are always determined alongside the unknowns and values quoted in the literature used for guidance only. In general, the lower the molecular weight or the more hydrophobic the carbohydrate the higher the R_f value.

Detection of carbohydrates for TLC is commonly based on dehydration and complexation after the chromatogram has been sprayed with an appropriate reagent and heated to 100–150 °C for 5–10 min. Suitable reagents include those based on diphenylamine/aniline/phosphoric acid or naphthoresorcinol/ethanol/sulfuric acid. A wide variety of colored responses is given, depending on the nature of the sugars present. TLC can be used semi-quantitatively using scanning densitometric analysis. The interpretation of such results may be misleading as color development will vary with spray technique, temperature and duration of heating and traces of salts, proteins and other impurities present in the sample.

TLC has been used to separate complex mixtures of cyclodextrins and their derivatives on silica gel.[14] Cyclodextrins, their glucosyl derivatives, and linear oligosaccharides were separated by eluting with mobile phases containing aqueous ammonia and either acetonitrile (ACN) or 1-propanol (Table 4). Compounds with different numbers of substituents on the cyclodextrins could be clearly separated, though the system did not allow separation of individual isomers.

Oligosaccharides may be purified on the milligram scale by high-performance thin-layer chromatography (HPTLC). HPTLC plates are available pre-coated from commercial suppliers, and are characterized by a much narrower particle size and particle size range resulting in improved resolution. Analysis by densitometry is also more satisfactory with HPTLC plates than conventional TLC plates.

5.1.2 High-performance Liquid Chromatography

For the qualitative and quantitative separation and analysis of mixtures of disaccharides and oligosaccharides the two most widely used techniques available to the researcher are HPLC and GC. The choice between the two methods is not often clear cut, but in general HPLC has been preferred for the separation and analysis of oligosaccharide mixtures, while GC has been used for more complex mixtures of monosaccharides and disaccharides. Recent advances in HPLC techniques, particularly in the type and sensitivity of detectors available, have seen it become the method of choice for many different types of analyses. In practice, though, GC is still in common use and there are many good examples of disaccharide and oligosaccharide separations in the literature.[15,16] SEC, used for the separation of polysaccharides and preliminary screening of mixtures of oligosaccharides and unknown samples, is discussed in section 6.1.

Table 4 Resolutions of cyclodextrins, their glucosyl derivatives, and linear oligosaccharides by TLC on Kieselgel 60

Compound	R_f (ACN system)[a]	R_f (propanol system)[a]
α-Cyclodextrin	0.18	0.21
β-Cyclodextrin	0.14	0.18
γ-Cyclodextrin	0.11	0.14
Glucosyl-β-cyclodextrin[b]	0.08	0.11
Maltosyl-β-cyclodextrin[b]	0.06	0.09
Dimaltosyl-β-cyclodextrin[b]	0.03	0.05
Glucose	0.23	0.31
Maltose	0.19	0.26
Maltotriose	0.15	0.24
Maltotetraose	0.12	0.19
Maltopentaose	0.09	0.15
Maltohexaose	0.07	0.12
Maltoheptaose	0.06	0.08

The term 'HPLC' is conventionally applied to columns having plate numbers above 2000, the typical range being 2000–20 000. For analytical applications, spherical packing materials generally offer better reproducibility and column stability over irregular-shaped particles. Particle sizes ranging from 3 to 20 μm are available. The most popular particle size for analytical columns is 5 μm, but the use of 3-μm particles in short columns is increasing. The retentivity and capacity of a packing material is related to its pore size. For most general analytical methods (analyte molecular weights less than 3 kDa) pore sizes of between 6 and 13 nm are typical.

The type and commercial availability of HPLC columns and detectors has expanded tremendously in recent years. For carbohydrate analysis the two most common types of packing materials are amino-bonded silica-based materials and metal-loaded polymeric substrates such as cross-linked styrene–divinylbenzene. The silica-based packing materials have a high rigidity and do not swell in any solvent. Their weakness is limited stability in aqueous mobile phases at high pH. The polymeric-based packings are more compressible, but they are compatible with all mobile phases including the entire aqueous pH range. Both the inorganic and the polymeric based materials offer a wide range of separation modes including reversed phase, ion exchange, hydrophilic interaction, hydrophobic interaction and SEC.

Some of the commercially available columns and typical analyses associated with them are given in Table 5. It should be borne in mind that there are many commercially available columns that will perform similar functions, and the list in Table 5 is by no means exhaustive. Choice of appropriate column for given separation is often due as much to personal experience, cost and availability of materials as choice of separation chemistry.

In reversed phase chromatography, where separation is by means of hydrophobic interactions, the stationary phase is nonpolar and the mobile phase is polar.[17] Typical stationary phases are silica-based bonded phases with aliphatic hydrocarbon ligands, for example octadecylsilane (ODS or C_{18}). Other packings for reverse phase chromatography include graphitized carbon or styrene–divinylbenzene. The mobile phase for carbohydrates is commonly a mixture of ACN and water. Graphitized carbon columns show exceptional physical and chemical stability and can be used throughout the

Table 5 Some commercially available HPLC columns and their modes of separation

Matrix[a]	Separation mode	Typical analysis	Mobile phase	Commercially available columns
Polymeric resins				
S-PS (Na^+ form)	Size exclusion and ligand exchange	Di-, oligo- and polysaccharides	Water	Shodex sugar KS (Showa Denko)
S-DVB (Ag^+ form)	Ion-moderated partition	Oligosaccharides	Water	Aminex HPX-42A (Bio-Rad)
	Ion exchange	Oligosaccharides	Water	Rezex RSO (Phenomenex)
S-DVB (Ca^{2+} form)	Ion-moderated partition	High-fructose corn syrup	Water	Aminex HPX-87C (Bio-Rad) Sugar-Pak 1 (Waters)
VA (NH_2 bonded)	Normal phase	Oligosaccharides	ACN–water	Asahipak NH2P-50 (Showa Denko)
Pellicular resin (Quaternary ammonium)	Ion exchange	Disaccharides Oligosaccharides	NaOH	CarboPak PA 10 (Dionex) CarboPak PA 100 (Dionex)
Methacrylate	Size exclusion	Polysaccharides	Water	TSK G4000 PW (TOSOH) Ultrahydrogel (Waters)
Silica				
(Amino-propylsilane bonded)	Reverse phase	Di-, and oligosaccharides	ACN–water	Carbohydrate (Waters) Partisil PAC (Whatman) LiChrosorb NH_2 (Merck) Capcell Pak NH_2 (Shiseido)
(Glycerylpropyl) (Organosilane)	Size exclusion	Oligo- and polysaccharides	Water	LiChrospher Diol (Merck) Zorbax SE-250 (Hewlett-Packard)
(β-Cyclodextrin)	Ligand exchange	Di- and oligosaccharides	ACN–water	Cyclobond 1 (Rainin)
Graphitized carbon	Hydrophobic interaction	Di- and oligosaccharides	ACN–water	Hypercarb (Shandon)

[a] Type of bonded phase or functional group is shown in brackets. VA, vinyl alcohol; S-PS, sulfonated polystyrene; S-DVB, sulfonated styrene divinyl benzene.

Figure 1 Separation of gluco-disaccharides on a Hypercarb column by linear gradient elution (0–15 min, 1 ml min^{-1}; pulsed amperometric detection (PAD), ambient temperature) with mM sodium hydroxide solution containing 1.5–5% ACN. 1, trehalose; 2, isomaltose; 3, kojibiose; 4, maltose; 5, nigerose; 6, gentiobiose; 7, sophorose; 8, cellobiose; and 9, laminaribiose. whole pH range. Such a column has been shown capable of separating nine isomeric disaccharides using gradient elution with dilute alkali containing small amounts of ACN (Figure 1).[18]

Separation based on hydrophilic interaction chromatography (HILIC) is another popular method of carbohydrate analysis.[19] HILIC uses polar stationary phases, such as microparticulate silica, with mobile phases ranging in polarity from water through ACN to hexane. Weak anion-exchangers based on bonded phase silicas containing primary, secondary and tertiary amines are the most common type of packing used for carbohydrate analysis. Retention increases with the hydrophilicity of the stationary phase and the hydrophobicity of the mobile phase. An alternative to using amino-bonded stationary phases for the separation of neutral oligosaccharides has been recently demonstrated using a β-cyclodextrins bonded phase column.[20] Separation of neutral oligosaccharides derived from starch, cellulose, pullulan, xylan, inulin, and mannan can be achieved using ACN–water mobile phases. Retention times are dependent on both the monosaccharide composition and glycosidic linkage type. The fast separation of inulin-derived oligosaccharides, up to DP 13, in ACN–water phases is demonstrated in Figure 2(a), with the effect of a higher ratio of ACN in the mobile phase shown in Figure 2(b). The β-cyclodextrin bonded phase column appears to have similar selectivity but greater durability compared to the amino-bonded phase silica gels. Ion-exchange chromatography,

Figure 2 Separation of inulin-derived oligosaccharide standards using (a) ACN–water (70 : 30, v/v) and (b) ACN–water (75 : 25, v/v). F = fructose, GF_2 = 1-kestose (DP 3), GF_3 = DP 4, etc. using a β-cyclodextrin bonded phase column (Cyclobond I, 250 mm × 4.6 mm i.d.); operated at room temperature and 1 ml min^{-1} flow rate with refractive index (RI) detection. S represents the solvent peak. (Reprinted from *J. Chromatogr., A*, **648**, 131–137, © 1993 with permission from Elsevier Science.)

based on strong anion-exchange resins (high-performance anion-exchange chromatography methods, HPAEC), is a powerful technique, which is discussed separately in section 5.1.3.

Monosaccharides, produced by enzymatic or chemical hydrolysis of polysaccharides, are often derivatized prior to HPLC analysis by the introduction of stable chemical groups such as 1-phenyl-3-methyl-5-pyrazolone (PMP). This can improve both resolution and sensitivity. A list of some common derivatives used is available in the article on **Monosaccharides and Sugar Alcohol Analysis**.

Ultraviolet (UV) detectors are not commonly used for carbohydrate analysis, though it is possible to monitor sugars directly at wavelengths below 200 nm. However at such short wavelengths, low sensitivity and background interference levels make the use of UV detectors often impractical. RI detectors work on the principle of differential refractometry and have, until recently, been the mainstay of HPLC carbohydrate detection. However, RI detectors are temperature dependent and cannot be used with a gradient, as they are extremely sensitive to changes in mobile phase concentration. RI can be useful for routine analysis of, for example, food samples where sensitivity in excess of 0.05% w/v is not generally required. If greater sensitivity is necessary then alternative detectors must be found. Pulsed amperometric detectors now offer much more versatility and sensitivity than RI detectors. These detectors are commonly used in tandem with anion-exchange chromatography, and are discussed in more detail in the next section.

5.1.3 High-performance Anion-exchange Chromatography Methods

In recent years HPAEC has become the method of choice for the separation of disaccharide and oligosaccharide mixtures. Coupled with PAD, HPAEC/PAD offers high resolution at picomole sensitivity. Specifically developed for the analysis of carbohydrates, HPAEC/PAD takes advantage of the weakly acidic nature of carbohydrates under alkaline conditions for highly selective separations on strong anion exchange resins. Anion-exchange chromatography of the partially ionized carbohydrates is carried out on polymeric, nonporous pellicular resins that are ideally suited to conditions of high pH. Separation is due to the degree of ionization of individual saccharides, but can also be based on anomers, positional isomers and molecular size. Retention times can be manipulated by altering the strength of the sodium hydroxide concentration or by addition of the more strongly eluting acetate anion. Typical analysis conditions will use mobile phase concentrations of 1–150 mM NaOH (pH 11–13) with gradient elution in sodium acetate for more strongly bound analytes.

Carbohydrates can be electrochemically oxidized at the surface of a gold or platinum electrode by the application of a positive potential (E_1). The initial current produced is proportional to the analyte concentration. As the oxidative carbohydrate products will lead to poisoning of the electrode surface over time, it is necessary to clean the electrode surface between measurements using a pulsed sequence of potentials. The electrode potential is raised to a sufficient degree to oxidize the surface and remove carbohydrate oxidation products (E_2). To reduce the surface back to gold, a third potential is then applied (E_3). A typical cyclic sequence for carbohydrate analysis by pulsed amperometry is shown in Figure 3.[21] Although Dionex were the first company to commercially manufacture pulsed amperometric detectors, a number of other companies now produce their own versions.

Figure 3 Typical cyclic sequence for pulsed amperometry. The potentials (E_1, E_2, E_3) and duration of the phases are shown.

Figure 4 HPAEC elution profile of the components of debranched wheat amylopectin on a HPIC-AS6 (250 × 4 mm i.d.) column using a gradient of 200 mM sodium acetate at the start, 250 mM at 2 min, 300 mM at 10 min and 400 mM at 40 min in 150 mM sodium hydroxide solution (1 ml min^{-1}; ambient. temperature) and PAD. The number on each peak indicates its DP. (Reprinted from *J. Chromatogr.*, **585**, 233–238, © 1991 with permission from Elsevier Science.)

The advantage of detection with PAD for carbohydrates is that no pre- or post-column derivatization is necessary. Sample preparation is also simplified because only oxidizable analytes will be detected by PAD, and the sensitivity for carbohydrates is orders of magnitude greater than for possible contaminant species.[21] Although HPAEC is often carried out at high pH, some separations are better carried out at neutral or acidic pH. While PAD sensitivity will decrease below pH 11, this problem can be circumvented by the post-column addition of base, usually 300–500 mM NaOH, to maintain pH through the detector. Unlike RI detectors, PAD is not sensitive to changes in salt concentration. It does show slight sensitivity to variable low NaOH concentrations such that post-column addition of base may also be necessary when running low concentration NaOH gradients.

There are a number of good reviews on HPAEC/PAD techniques in the literature.[22,23] The technique has been used to estimate the chain length of different amylopectins after enzymatic digestion by isoamylase (Figure 4).[24] Although the relative detector response changes with the DP, this can be overcome by using saccharides with appropriate chain lengths as standards. Recently a method coupling SEC with HPAEC has been developed to distinguish between highly branched and linear oligoglucans, as well as linear isomeric gluco-oligosaccharides.[25] This method may be very useful in overcoming problems separating smaller oligosaccharides from the larger polymeric mass during the early stages of enzymatic digestion of polysaccharides.

5.1.4 Capillary Electrophoresis

Capillary electrophoresis (CE) is a relatively new technique that provides rapid, highly efficient separations for carbohydrates.[26,27] Electrophoresis is the movement of charged substances in a conductive medium, usually aqueous, under the influence of an applied electric field. Charged species are separated on the basis of their electrophoretic mobility (charge : mass ratio) and the electroosmotic flow (migration of positive buffer ions to the cathode under the influence of the applied field). Separation can be manipulated by changing either buffer composition or pH. The technique is also applicable to neutral polysaccharides, which can be charged either through complexation with for example borate ions, or by raising the pH of their microenvironment. CE is complimentary to separation of oligosaccharides by GC and HPLC techniques. Like HPLC, it is suited to the analysis of both polar and nonpolar carbohydrates and it may replace many of the HPLC techniques in the near future. CE offers fast and efficient separation, relatively affordable and durable capillary columns, requires small sample volumes and has low reagent consumption. However, it is not generally useful for preparative scale applications.

CE is available in a number of modes including capillary zone electrophoresis (CZE), isoelectric CE, and micellar electrokinetic CE. Typical CE equipment consists of high-voltage power supply, buffer reservoirs, a capillary column, and a detector. CE is usually performed using fused silica capillaries that are 50 or 70 μm i.d., 375 μm o.d. and between 30 and 100 cm long. Fused silica capillaries are commercially available from a number of suppliers and much longer ones have been used in GC for a number of years. The major limitation in the use of CE for carbohydrate analysis, as with other techniques, has been detector sensitivity. Advances in separation and detection techniques in the last five years including PAD and fluorescence detection has seen yoctomole (10^{-24} mole) sensitivity become a realistic target.[28]

Figure 5 CZE of a mixture of oligosaccharides (a) and partially purified pea extract (b), using the following separation conditions: 100 mM $Na_2B_4O_7$, pH 9.9, 50 °C, 10 kV. S, sucrose; R, raffinose; ST, stachyose; V, verbascose; A, ajugose; L, lactose; M, melibiose; W, water front; U, unknown; F, 'false peak'. (Reprinted from *J. Chromatogr., A*, **652**, 517–524, © 1993 with permission from Elsevier Science.)

Separation of the raffinose family of oligosaccharides (Figure 5) has been demonstrated using the capillary zone method of electrophoresis, where the carbohydrates are charged using their cis-diol borate complexes.[29] Partial purification using ion exchangers before CZE appeared essential to achieve good separation (Figure 5b). Separation by high-performance CE of the borate-complexed oligosaccharides offered several advantages over HPLC separation using RI methods, including on-column UV detection, ease of operation, low cost per analysis and the use of nontoxic chemicals.

5.2 Methylation Analysis

Methylation analysis is one of the most commonly used techniques in structural carbohydrate chemistry.[30] Methylation analysis will give information on the positions at which sugar residues are substituted and their relative abundance in the polysaccharide, though it gives no information on the sequence that these residues appear in, nor on their anomeric conformation. Methylation analysis involves methylation of all the free hydroxyl groups in the polysaccharide, hydrolysis of the methylated polysaccharide to its component parts, reduction of these methylated monosaccharides to alditols, acetylation of the alditols, and subsequent qualitative and quantitative analysis of the partially methylated alditol acetate derivatives by GC or GC/MS. The positions of the free hydroxyl groups in the partially methylated sugars indicate where the residue was substituted.

The main problems associated with the technique are incomplete methylation of the polysaccharide, oxidative degradation of some hydroxyl groups and contamination from 'impure' reagents and solvents. Methylation analysis is commonly based on a modification of the Hakomori procedure, where alkoxide groups are readily generated by the presence of a strong nucleophile ensuring complete methylation of all free hydroxyl groups.[31] The polysaccharide is dissolved in dry dimethyl sulfoxide (DMSO) in the presence of a strong base such as sodium hydride, 1-butyl lithium, potassium *tert*-butoxide or powdered sodium hydroxide generating production of the dimsyl anion. Methylation of the alkoxide groups is usually carried out with methyl iodide (Scheme 1). Latterly methods based on the use of potassium dimsyl have become more widespread, and it is reported to give at least equal or better results than the sodium salt.[32] At the end of the methylation reaction, water is added and the polysaccharide can be recovered from the aqueous phase after extraction with chloroform. The methylated polysaccharide is then reduced to its component sugars by hydrolysis (trifluoroacetic, hydrochloric or sulfuric acid may be used). At this stage the components have free hydroxyl groups in the positions where they were linked to each other and methyl ether groups where the original polysaccharide had free hydroxyl groups. Reduction of the methylated monosaccharides in sodium borodeuteride, to label the reducing ends, is followed by peracetylation with acetic anhydride in pyridine (1 : 1 v/v). Finally the volatile, partially methylated alditol acetates are analyzed by GC coupled to a mass spectrometer (GC/MS, see Scheme 1).[33]

For oligosaccharide substrates it is often advantageous to convert the reducing termini of the oligosaccharides to their alditols before methylation, in order to reduce side reactions.

5.3 Periodate Oxidation

Periodate oxidation is another important tool in structural polysaccharide chemistry and can be used to determine glycosidic linkage. In the first step periodate oxidizes adjacent hydroxyl groups in carbohydrate residues. Formic acid is produced when the polysaccharide unit contains three hydroxyl groups on adjacent carbon atoms. Oxidation is followed by reduction to polyalcohols with sodium borohydride followed by mild acid hydrolysis.

Scheme 1 Methylation analysis of glycan: methylation of all free hydroxyl groups using dimsyl anion and methyl iodide (1) is followed by hydrolysis of the methylated polysaccharide to its component sugars (2), reduction with sodium borodeuteride and acetylation with acetic anhydride (3). The major cleavage fragments of the partially methylated alditol acetate as analyzed by GC/MS are shown (4). Other fragments arise from these by elimination of neutral molecules such as acetic acid (−60.0 Da) and methanol (−32.0 Da).

Scheme 2 Periodate oxidation of 1,4 α-linked glucan: oxidation of the glucan with sodium periodate (1) is followed by reduction with sodium borohydride (2). After acid hydrolysis (3) the products can be derivatized and analyzed by GC.

Degradation of periodate-oxidized amylose, after reduction and hydrolysis, is demonstrated in Scheme 2. Since periodate oxidation requires adjacent free hydroxyls, if the glucan in Scheme 2 was (1 → 3)-linked then only the terminal residues at both the reducing and nonreducing ends would be oxidized. Periodate oxidation is normally carried out in the pH range 3–5 to avoid acid hydrolysis and to minimize side-reactions involving nonselective oxidations. Periodate can cause over-oxidation of certain products causing misinterpretation of results. Where the main structural features of a polysaccharide are already known, periodate oxidation can be a useful method.

An important modification of this procedure, the Smith degradation, selectively degrades polysaccharides to oligosaccharides or smaller polysaccharides. Controlled hydrolysis with dilute acid is carried out at ambient temperatures. The acetals of oxidized sugar rings are the most labile during the hydrolysis step. The products may range from the low-molecular-weight products shown in Scheme 2 to monosaccharide, oligosaccharide and polysaccharide glycosides that can be usefully put through the procedure again.

5.4 Hydrolysis with Specific Glycosidases

Glycosidases are an important tool in structural determination because of their ability to specifically cleave carbohydrate linkages in disaccharides, oligosaccharides and polysaccharides. It is their ability to cleave specific

Table 6 Specificity of some important glycosidases used in polysaccharide analysis

Common name	Enzyme commission (EC) number	Specificity
α-Amylase	3.2.1.1	Internal hydrolysis of α-(1 → 4)-glucans
β-Amylase	3.2.1.2	Terminal hydrolysis of maltose from α-(1 → 4)-glucans
Glucoamylase	3.2.1.3	Terminal hydrolysis of α-linked glucose units
Cellulase	3.2.1.4	Internal hydrolysis of β-(1 → 4)-glucans
Inulinase	3.2.1.7	Internal hydrolysis of β-(2 → 1)-fructans
Endo–β-xylanase	3.2.1.8	Internal hydrolysis of β-(1 → 4)-xylans
Dextranase	3.2.1.11	Internal hydrolysis of α-(1 → 6)-glucans
Chitinase	3.2.1.14	Internal hydrolysis of *N*-acetyl-β-(1 → 4)-glucosamine links in chitin
Polygalacturonase	3.2.1.15	Internal hydrolysis of galacturonic acid in pectins
α-Glucosidase	3.2.1.20	Terminal hydrolysis of α-linked glucose
β-Glucosidase	3.2.1.21	Terminal hydrolysis of β-linked glucose
α-Galactosidase	3.2.1.22	Terminal hydrolysis of α-linked galactose
β-Galactosidase	3.2.1.23	Terminal hydrolysis of β-linked galactose
α-Mannosidase	3.2.1.24	Terminal hydrolysis of α-linked mannose
β-Mannosidase	3.2.1.25	Terminal hydrolysis of β-linked mannose
Invertase	3.2.1.26	Terminal hydrolysis of β-linked fructofuranose
N-Acetyl-β-glucosaminidase	3.2.1.30	Terminal hydrolysis of β-linked Glc*N*Ac in glycans
β-Glucuronidase	3.2.1.31	Terminal hydrolysis of β-linked glucuronic acid in polysaccharides
β-Xylosidase	3.2.1.37	Terminal hydrolysis of β-linked xylose
Pullulanase	3.2.1.41	Hydrolysis of reducing terminal α-linked L-arabinose
α-L-Arabinofuranosidase	3.2.1.55	Hydrolysis of α-(1 → 6)-linked glucose in predominantly α-(1-4)-glucans
Levanase	3.2.1.65	Internal hydrolysis of β-(2 → 6)-fructans
Isoamylase	3.2.1.68	Internal hydrolysis of α-(1 → 6)-linked glucose in predominantly α-(1-4)-glucans
β-Mannanase	3.2.1.78	Internal hydrolysis of (1 → 4)-linked mannose in mannans, galactomannans and glucomannans

residues without side-reactions, yielding unmodified oligosaccharides that is important for the determination of native polysaccharide structure. Mixtures of di- and oligosaccharides can then be separated and identified by column chromatography and NMR. Knowledge of the mode of action of the enzymes used allows a prediction for native polysaccharide fine structure. This technique is hindered only by the availability of suitable, single-activity enzymes. Complete hydrolysis of a complex polysaccharide will involve the use of more than one type of enzyme. A list of some of the glycosidases commonly used in polysaccharide analysis is given in Table 6.

6 MOLECULAR WEIGHT ANALYSIS

Oligosaccharides and polysaccharides usually possess one, and only one, reducing end group per molecule. Where these can be quantified, the number of molecules present can be determined. If the total carbohydrate present is also determined, the average chain length and the molecular weight may be calculated. There are very sensitive colorimetric assays available for reducing end groups including the use of oligosaccharide dehydrogenase, an enzyme specific for reducing end groups.[34] Alternatively, quantitative ^{1}H NMR using the terminal anomeric reporter groups may determine them. These methods allow molecular weights up to about 20 kDa (NMR) to over 100 kDa (colorimetric) to be determined. However, the presence of even tiny amounts of monosaccharide impurities may render the result invalid due to the number averaging of the resultant molecular weights.

The molecular weight (M) of pure macromolecules may be determined by ultracentrifugation, so long as both the sedimentation coefficient (s) and the diffusion coefficient (D) are determined under the same conditions, using the relationship shown in Equation (1).

$$\frac{s}{D} = \frac{M(1 - \bar{v}\rho)}{RT} \tag{1}$$

where T is the temperature (K), R is the gas constant, $\bar{v}$ is the partial specific volume (the effective volume per unit mass) of the solute and ρ is the solution density. Although this method is still sometimes used, the method remains arduous compared with SEC and laser LS methodology.

6.1 Size Exclusion Chromatography

SEC has proved to be a useful technique for separating carbohydrates on the basis of their molecular weight.[35] Molecules are eluted in order of decreasing molecular size from a stationary phase containing a wide range of different size pores, allowing greater access and hence slower elution for smaller molecules. SEC is particularly successful in separating members of oligosaccharide families where it often allows the exact number of component sugars to be determined (Figure 6). Where the oligosaccharides come from a mixture of oligosaccharide families, the assignment of molecular size is less reliable in the absence of known standards. SEC is less successful at determining the molecular size of polysaccharides where it depends on the use of similar carbohydrates, of known molecular weight, for calibration. Unless these molecules are monodisperse and have almost identical structures to those of the unknowns, the resultant calibration may be grossly in error. This has been shown to be the case where the molecular weights can be independently determined by, for example, LS (see section 6.2). Use of secondary calibration in the SEC, where polysaccharides of known molecular weight but dissimilar structure are used, has been shown to overestimate the molar mass of chitosans[36] and capsular polysaccharides by two- and threefold (Figure 7).[37] Improvement can be made if 'universal calibration' is used involving the use of the product of the intrinsic viscosity and the molecular weight ($\eta\overline{M}_w$, a measure of the dynamic volume of the polysaccharide) in place of the molecular weight alone.[38] However, this involves the additional use of a viscometric detector and gives incorrect results if the calibrating and unknown polysaccharides are of different conformational types (e.g. random coil versus stiff rod). Although high-performance size exclusion chromatography (HPSEC) uses columns having theoretical plate numbers of about 10 000, even under optimal conditions they are only capable of resolving polysaccharide peaks where there is at least a twofold difference in molecular weights or sizes present. There are two reasons for this: (1) the resolving power of SEC columns is relatively poor for high-molecular-weight polysaccharides, and (2) such polysaccharides usually consist of a range of molecular species with a wide molecular weight distribution. In spite of these limitations, SEC is proving to be a powerful technique for the analysis of polysaccharide polydispersity when used in combination with on-line LS molecular weight determination.

6.2 Light Scattering

Light is scattered from molecules in solution in a way that depends on the concentration and molecular size of the molecules present. This has been known for over 50 years

Figure 6 Separation of oligomeric arabinoxylans by SEC on a Bio-Gel P-2 at 60 °C. The number of the fraction corresponds to its DP. Fractions 1–3 are xylose, xylobiose and xylotriose respectively, Fractions 4–10 are mainly Xyl_3Ara, Xyl_4Ara, Xyl_5Ara/Xyl_4Ara_2, Xyl_5Ara_2, Xyl_6Ara_3/Xyl_7Ara_2, Xyl_6Ara_4/Xyl_7Ara_3, respectively. (Reprinted from *Carbohydr. Res.*, **249**, 369–382, © 1993 with permission from Elsevier Science.)

Figure 7 Comparison of molar-mass determination of capsular polysaccharide fractions by SEC using dextrans for calibration and by multiangle laser light scattering (MALLS). (Reproduced from D'Ambra et al.[37] by permission of Academic Press, Inc.)

but it is only recently that methods have become widely used for polysaccharides. In particular the use of MALLS has enabled the accurate nondestructive determination of the molecular weight, molecular weight distribution and radius of gyration of many polysaccharides without the need for known calibrating standards. When combined with the separating power of HPSEC, it forms an

important tool for the polysaccharide analyst. A typical SEC/MALLS system includes an RI detector, placed after the MALLS detector, for determining the concentration of the eluting polysaccharides. Generally there is no need for the simultaneous UV detection, which is so useful in the SEC/MALLS of proteins, as polysaccharides rarely possess absorbing groups.

LS from molecules in solution is described by Equation (2).[39]

$$\frac{Kc}{R_\theta} = \frac{1}{M_w}\left(1 + \frac{16\pi^2}{3\lambda^2}\langle r_g^2\rangle \sin^2\left(\frac{\theta}{2}\right. \right. + f_4 \sin^4\left(\frac{\theta}{2}\right. \quad + \cdots \quad + 2A_2c \tag{2}$$

where:

K is an optical parameter given in Equation (3).

$$K = \frac{4\pi^2 n^2 (\mathrm{d}n/\mathrm{d}c)^2}{\lambda^2 N_A} \tag{3}$$

c is the sample concentration, calculated from the differential RI response, R_θ is the excess intensity of scattered light at angle θ, and M_w is the weight average molar mass (molecular weight, Equation 4).

$$M_w = \frac{\sum_i n_i M_i^2}{\sum_i n_i M_i} \tag{4}$$

where M_i is the mass of the ith polysaccharide chain and n_i is the number of chains with that mass.

λ is the wavelength of the scattered light in vacuum. A_2 is the second virial coefficient, a measure of the solute solvent interaction. The $2A_2c$ term is usually negligible in SEC separations due to typically low concentrations. A_2 is characteristically about $1–2 \times 10^{-5}$ mol ml g^{-2}. At polysaccharide (M_w 10^6) concentrations of about 1 mg ml^{-1}, ignoring this term gives about a 2–4% error. It may, however, be significant for charged polysaccharides at low ionic strength.

N_A is Avogadro's number, n is the RI. ($\mathrm{d}n/\mathrm{d}c$) is the RI increment of the solute, which is usually determined prior to HPSEC using a range of polysaccharide concentrations. This value varies between polysaccharides and is somewhat less (~0.13–0.15 ml g^{-1}) than that for proteins (~0.18–0.19 ml g^{-1}).

$\langle r_g^2\rangle$ is the z-average mean square of the radius of gyration (R_G, Equation 5)

$$R_G^2 = \langle r_g^2\rangle = \frac{\sum_i n_i M_i^2 \langle r_g^2\rangle_i}{\sum_i n_i M_i^2} \tag{5}$$

R_G reflects the average displacement of each residue from the molecular centre. Typically for a linear polysaccharide (M_w 10^6) this would be approximately 6 nm if spherically packed (R_G = radius $\times \sqrt{3/5}$), 940 nm if as an extended stiff rod (R_G = length/$\sqrt{12}$), and 17 nm (R_G = unit length $\times \sqrt{\text{units}/6}$) if as a random coil. The $\sin^4(\theta/2)$ and higher terms (not shown in Equation 2) are not explicitly used as the determination of the molar mass and the radius of gyration involve extrapolation to zero angle. For smaller molecules with R_G up to 10 nm, the $\sin^2(\theta/2)$ term is ignored as well as this simplification only introduces errors of less than about 1%. The lack of sensitivity to scattering angle at low R_G means that it cannot be accurately determined when smaller than about a sixtieth of the wavelength of the light used (i.e. <10 nm). Ignoring this term in $\sin^2(\theta)$ allows single-angle LS (Equation 6) data (often at 90°) to be used.

$$\mathrm{LS} = K_{LS} c M_w \left(\frac{\mathrm{d}n}{\mathrm{d}c}\right.^2 \tag{6}$$

where K_{LS} is a detector calibration constant. As the RI signal (Equation 7) is given by

$$\mathrm{RI} = K_{RI} c \left(\frac{\mathrm{d}n}{\mathrm{d}c}\right. \tag{7}$$

where K_{RI} is the instrumental calibration constant, the molar mass (M_w) can be determined from these two readings once the polysaccharide's RI increment has been determined (Equation 8).

$$\frac{1}{M_w} = K' \frac{\mathrm{d}n}{\mathrm{d}c}\frac{\mathrm{RI}}{\mathrm{LS}} \tag{8}$$

K' is a calibration constant determined by using previously characterized similar polysaccharides.

At low angles, the angular dependence of LS depends only on the radius of gyration and is independent of molecular conformation or branching. This is of particular benefit in the study of polysaccharides, which may take up a wide variety of conformations in solution. Often the molecular weight and radius of gyration are determined by plotting (Kc/R_θ) against $\sin^2(\theta/2)$ (Zimm plot) to yield an often almost linear curve whose intercept gives M_w and whose slope at low angles gives $\langle r_g^2\rangle$. For branched polysaccharides the radius of gyration can provide a measure of the degree of branching if similar but unbranched polysaccharides are available. When repeated at various polysaccharide concentrations, or across a SEC run, other parameters such as the number average molecular weight ($\overline{M}_n$, Equation 9), polydispersity (Equation 10), molecular weight distribution and weight-averaged radius of gyration ($\overline{R}_G$, Equation 11)

may also be determined.

$$\overline{M}_n = \frac{\sum_i n_i M_i}{\sum_i n_i} = \frac{\sum_i c_i}{\sum_i \frac{c_i}{M_i}} \quad (9)$$

$$\text{polydispersity} = \frac{\overline{M}_w}{\overline{M}_n} \quad (10)$$

$$\overline{R}_G^2 = \overline{\langle r_g^2 \rangle} = \frac{\sum_i n_i M_i \langle r_g^2 \rangle_i}{\sum_i n_i M_i} = \frac{\sum_i c_i \langle r_g^2 \rangle_i}{\sum_i c_i} \quad (11)$$

M_w is always greater or equal to M_n so the polydispersity, which measures the breadth of the molecular weight distribution present, is always greater or equal to unity.

MALLS detectors simultaneously measure the LS at a number of angles and extrapolate via software to zero angle. There are also low-angle laser light scattering (LALLS) devices which only measure at very low angles (~3–7°). The choice between these systems depends on a number of factors including sensitivity to extraneous noise. It has been found that, for most polysaccharides, the molecular weights vary across HPSEC peaks (Figure 8). Molecular weights of polysaccharides that are insoluble in water can be determined using MALLS with other solvents (e.g. DMSO) without necessarily using HPSEC.

Figure 8 HPSEC/MALLS of maize starch. The HPSEC was performed using two columns (TSK gel G4000 SWXL 7.8 mm i.d. × 30 cm and TSK gel G3000 SWXL 7.8 mm i.d. × 30 cm, TosoHaas) in series at 30 °C. (· · · · ·) LS, volts; (- - - - -) RI, volts; (————) molecular weight (M_w) from MALLS. Note that the second peak is almost lost using LS as this depends not only on concentration but also on molecular size. (Reproduced from Bello-Pérez et al.[55] with permission of Academic Press, Inc.)

Even highly insoluble polysaccharides such as cellulose may be analyzed (e.g. in dimethylacetamide containing LiCl), if they can be dissolved in suitable solvents, although such solvents may not be compatible with the HPSEC matrices. MALLS detection may be used in conjunction with other HPLC separation techniques (e.g. reverse phase chromatography) but as it determines the weight-averaged molecular weight it will give less meaningful results if a wide range of molecular masses, or few species but with very disparate molecular masses, are present. MALLS can also be used for determining the molar mass and molecular weight distribution of oligosaccharides.[40]

7 PHYSICAL METHODS OF ANALYSIS

7.1 Mass Spectrometry

MS was one of the first methods used to investigate carbohydrate structure. Its principle of operation is to create gas-phase ions, separate them in space or time based on their mass-to-charge (m/z) ratio and to quantify them. Originally it assisted in linkage analysis by identifying the methylated alditol acetates produced in the methylation analysis of glycans and separated by GC. The electron impact/mass spectrometry ionization method (EI/MS), often utilized in GC, is highly energetic causing extensive degradation and, usually, the absence of molecular ions. This lack of molecular ions is of little importance as it is the fragmentation pattern that is so important to methylation analysis, clearly demonstrating which hydroxyl groups were free and have been methylated, and which were involved in linkages and have been acetylated. As EI/MS requires volatile samples, oligosaccharides are too polar unless derivatized. Development of the gentler fast atom bombardment ionization source allows oligosaccharides, both derivatized and underivatized, to be analyzed in a similar manner but where molecular ions and large fragments, produced by cleavage between the glycosidic units, are produced. The reducing end of oligosaccharides can be labeled with ^{18}O for MS by catalyzed exchange with $H_2{}^{18}O$ (e.g. by using 2-aminopyridine or other epimerization catalyst), enabling fragments involving this end to be distinguished. Larger oligosaccharides and polysaccharides may make use of the even milder ionization techniques involving matrix assisted laser desorption ionization (MALDI) and electrospray ionization (ESI). As these produce molecular ions without interference from breakdown products, the molecular weight distribution can be clearly demonstrated. MS must be combined with other methods of analysis, as it cannot distinguish between isomeric sugar residues and cannot easily provide the linkage and stereochemical information of NMR.

7.1.1 Fast Atom Bombardment/Mass Spectrometry

FAB/MS (fast atom bombardment/mass spectrometry) can be used optimally on nanomolar amounts of oligosaccharides and small polysaccharides up to about 15 kDa[41] although usually requiring microgram amounts of oligosaccharides of less than about 5 kDa. Xe or Cs ion or Xe atom guns are all suitable for carbohydrates. Carbohydrates are generally, but not necessarily, derivatized by permethylation or peracetylation as then they are easier to purify, the sensitivity is improved by as much as two orders of magnitude and the fragmentation pattern is more predictable. However, the use of underivatized carbohydrates removes the risk of any loss of labile substituents. The spectra usually contain the molecular ions, which may be protonated or cationized with ammonium, sodium or potassium. This allows cyclic glycans, such as the cyclodextrins, to be identified, as their molecular mass is 18 (H_2O) less than the corresponding linear glycan. The major inter-glycosidic fragmentation processes may result in hydrolytic-like fragments from either side of the glycosidic link or elimination-like oxonium ion fragments from the anomeric side only (Scheme 3). Two fragmentation pathways dominate the spectrum. Permethylated and peracetylated glycans cleave on nonreducing side of glycosidic bonds to give oxonium ions (Scheme 3a), a cleavage that is particularly favored by *N*-acetyl-hexosamines. Native carbohydrates commonly give β-cleavage where a hydrogen atom is taken from the neighbor glycoside and retained on either the reducing (Scheme 3b) or nonreducing end (Scheme 3c). The residue masses are given in Table 7. Linkage analysis can be achieved from FAB/MS by the analysis of rarer cross-ring fragmentation products or by utilizing partial

Scheme 3 The major inter-glycosidic fragmentation processes. (a) 'A type' cleavage; (b) β-cleavage with charge retention on the reducing end; (c) β-cleavage with charge retention on the nonreducing end. In β-cleavage the hydrogen atom has been abstracted from the position β to the glycosidic oxygen on the uncharged fragment and producing an enol/keto group (e.g. the 3-position in (b) and the 2-position in (c)) in unmethylated oligosaccharides.

Table 7 Exact mass data for carbohydrate residues in oligosaccharides and polysaccharides utilizing the most abundant isotopes; also given is the maximum number of free hydroxyl groups if the residues are not terminal (there will be one more if terminal) and the extra mass involved for each additional methylated and acetylated group

Residue	Exact mass	Hydroxyls available
Pentose	132.0432	2
Hexose	162.0528	3
Deoxyhexose	146.0579	2
Hexuronic acid	176.0321	3
N-Acetyl hexosamine	203.0794	2
N-Acetyl neuraminic acid	291.0954	4
O-Methyl replacing hydroxyl group	14.0157	
O-Acetyl group replacing hydroxyl group	42.0106	
Nonreducing end	1.0078	
Reducing end	17.0027	
^2H replacing ^1H	1.0063	
^{18}O replacing ^{16}O	2.0042	

acid or enzyme hydrolysates. Anomeric configurations can be determined by FAB/MS due to the different rates of their chromium trioxide oxidation in peracetylated oligosaccharides, β-linkages are equatorial and are more rapidly oxidized than α-linkages so forming a keto-ester, breaking the ring, and resulting in a mass change of +14 (+O −2H).

7.1.2 Matrix-assisted Laser Desorption Ionization Mass Spectrometry

MALDI can vaporize and ionize large molecules and is capable of determining molecular weights, in exceptional cases, of up to *m*/*z* 300 kDa using time-of-flight (TOF) detection. It requires only femtomoles to picomoles of material, needs no sample derivation and tolerates more buffer and detergent than other MS methods. Although able to handle proteins, it has not had similar success, so far, with natural polysaccharides in the upper part of this range (>25 kDa) and seems to work best with oligosaccharides below 5 kDa (Figure 9). This may be partly due to the polydispersity of such samples and the inherently poor resolution of MALDI/TOF/MS.

MALDI ionizes by using a UV laser pulse to ablate a UV-absorbing matrix which carries some of the large molecules into the gas phase in an ionized form. The matrix commonly used for carbohydrates is 2,5-dihydroxybenzoic acid (DHB), although several other matrices (e.g. 3-aminoquinoline, α-cyano-4-hydroxycinnamic acid, 2-hydroxy-5-methoxybenzoic acid, 2,6-dihydroxyacetophenone) are often tried in order

Figure 9 MALDI/MS of mixed isomeric onion (*Allium cepa* L.) fructan oligosaccharides showing the DP of the predominant monosodium adduct ions $[M + Na]^+$. The difference between sequential peaks is 162.1 Da. (Reproduced from Stahl et al.[56] with permission of Academic Press, Inc.)

to optimize the spectra. Anions, such as sulfate, are added by some workers in order to obtain negatively charged ions, which are analyzed by MS using the negative mode. The matrix is usually present in about a hundred-fold molar excess over the carbohydrate. Intact oligosaccharides can be recovered and sequenced directly, by MALDI/TOF, from sodium dodecyl sulfate/polyacrylamide gel electrophoresis (SDS/PAGE) separated glycoproteins.[42] Gel pieces containing glycoprotein are denatured, reduced *S*-alkylated and endoglycosidase digested, then extracted with water, cleaned up using micro-columns, dried and subjected to MALDI/TOF. Neutral oligosaccharides give $[M + Na]^+$ and smaller $[M + K]^+$ peaks. Acidic residues, such as sialic and uronic acids, form both positive and negative ions and readily form salts with alkali metal ions resulting in multiple peaks. These adverse effects may be overcome by prior esterification.

The mass accuracy of MALDI (0.1–0.01%) is generally lower than other MS methods, but the recent linking of the method to collision-induced dissociation/Fourier transform mass spectrometry (CID/FTMS) extends this to 0.001% for oligosaccharides.[43]

7.1.3 Electrospray Ionization/Mass Spectrometry

ESI allows production of molecular ions directly from samples in solution and is thus suitable for direct interfacing to HPLC and CE. It is far less able to handle buffers and detergents than MALDI. Multiply charged ions are usually produced which is an advantage on naturally multiply charged proteins and glycoproteins (up to about 150 kDa) but a disadvantage on polydisperse neutral glycans. Although ESI has good sensitivity (picomole) and accuracy (0.005%), the *m*/*z* range of their normal quadrupole detectors is only up to 3 kDa allowing its use only on glycopeptides and smaller oligosaccharides and lipopolysaccharides.

7.1.4 Tandem Mass Spectrometry

Tandem mass spectrometry (MS/MS) utilizes two or more mass selection devices in series so that the known ion from one analyzer may be selected and induced to give daughter fragments which are determined using a second analyzer. It can provide complete sequence, branching and linkage information.[44] If higher energy collision-induced dissociation (CID) is achieved, the choice between pyranose and furanose ring systems may be distinguished due to carbon–carbon bond cleavage of the side chain leaving ring oxonium ions.

MS/MS can be used with FAB (fast atom bombardment), ESI[45] and MALDI. The use of post-source decay (PSD) in MALDI/TOF is proving particularly useful for the linkage analysis of complex oligosaccharides where a database of spectral information can be built up, such as with glycoprotein *N*-glycans.[46] Similar data can be obtained by ESI CID. This is because the extent and distribution pattern of fragments is highly reproducible. Multiple fragmentation occurs inter-glycosidically with retention of Na^+ cationized charge on either the reducing or nonreducing fragment in a similar manner to that in FAB/MS (see section 7.1.1).

7.2 Nuclear Magnetic Resonance Spectroscopy

NMR is proving to be the most powerful technique for the structural analysis of oligosaccharides and polysaccharides. It is particularly useful in finding unusual and unusually substituted sugars. Each proton (^1H nucleus) attached directly to carbon in a monosaccharide has its own characteristic environment. However as the number of carbohydrate units increases in the molecule so does the number of magnetically distinct nuclei. Pentoses and hexoses in oligosaccharides and polysaccharides have eight or ten distinct protons per residue, respectively. Two or three, respectively, of these are associated with alcohol hydroxyl groups. This means that they have approximately the same number of protons as proteins of similar size; significantly more if the hydroxyl protons are counted in. They also have approximately the same number of carbon atoms. Nitrogen atoms are absent in most oligosaccharides and polysaccharides but, even where present in large amounts (e.g. in chitosans), there are significantly fewer than in similarly sized proteins. ^1H and ^{13}C NMR spectra of carbohydrates may, therefore, be extremely complex. Additionally, many of these environments are often similar, giving a poor spectral dispersion with overlapping resonances. As in protein NMR, the low natural abundance of ^{13}C (1.11%) and ^{15}N (0.37%) and

these isotopes' lower natural sensitivities compared to ^{1}H (^{13}C, 1.6%; ^{15}N, 0.1%), means that NMR utilizing these atoms is much improved if the carbohydrate has been isotopically enriched.

The key features of carbohydrate NMR are due to the downfield shifts (to higher ppm) due to the spatial proximity of oxygen atoms. As the anomeric carbon is bonded to two oxygen atoms, the anomeric (C-1) carbon (^{13}C) atoms and protons are easily distinguishable and provide important inroads into the structural determination. Other groups also provide well-resolved resonances. The methyl protons and carbon (^{13}C) atoms in deoxysugars are upfield (i.e. at lower ppm) and the carboxylate carbon (^{13}C) atoms in uronic acids are downfield. Free amino groups give pH dependent shifts, upfield of hydroxyls, whilst *N*-acetyl and *O*-acetyl groups give upfield methyl groups.

In NMR the quality of the spectrum depends on two relaxation times. The longitudinal relaxation time T_1 (seconds) describes the rate at which the magnetization returns to equilibrium along the magnetic field (z direction) and correlates with the overall rotational tumbling of the carbohydrate and its intramolecular flexibility. The transverse relaxation time T_2 (seconds) describes the rate of decay of the effective magnetization observed in the receiver (xy directions) and correlates with the dynamic properties of the molecule (e.g. it reduces with increasing molecular size). Line width is inversely proportional to T_2. The large size of polysaccharides leads to slow tumbling, hence broad lines due to fast T_2 spin–spin relaxation. This reduces the sensitivity, broadens the spectral lines and generally results in poor performance of 2-D techniques that incorporate delays to allow coherence (same phase) transfer. Although spectral improvements can be achieved by heating (~70–85 °C), albeit with the introduction of extra 'noise', this may have conformational consequences. For example, multihelical structures give very poor spectra, which can be improved by heating and/or alkali but the treatment results in them having a different conformation. Cations (e.g. Ca^{2+}) may also cause gelling with carboxylic-acid-containing polysaccharides, so reducing performance. A high viscosity is also associated with poor NMR spectra. In general, the larger the polysaccharide, the less resolved its NMR spectrum. Resolution may be improved by partial hydrolysis (e.g. 10 mM HCl, 100 °C, 10 min) but this may give fragments that are not representative of the original structure. For example, partial acid hydrolysis of arabinoxylans strips off the labile arabinofuranose groups leaving bare β-xylan chains. If available, partial hydrolysis using well-characterized endo-glycosidases is preferred.

Polysaccharides are usually run in D_2O ($^{2}H_2O$). Working in D_2O eliminates the less well-defined exchangeable hydroxyl protons and the vast excess (110 M) of H_2O protons, although significant HOD (4.4 mM) resonance remains even in 99.996% D_2O solution. Intramolecular hydrogen bonding may be investigated by dissolving the carbohydrate in per-deuterated DMSO when the hydroxyl (and amine) protons do not exchange with solvent and give useful information. It must be noted, however, that sugars may behave differently in this solvent than in aqueous solution. Inter-residue hydrogen bonding is important in determining the overall conformations of carbohydrates but is difficult to determine by NMR. In some cases hydrogen bonding may be determined from proton exchange in mixed $^{1}H_2O$ and $^{2}H_2O$ solvents where solvent exposure may be quantified from the differential shifts in proton and carbon spectra.

The anomeric protons can provide information concerning the types of residues present, their anomeric (α or β) configuration and their ring size (pyranose or furanose). Details of the NMR spectra of many carbohydrates are available from a database.[47] Although 1-D proton NMR spectra can be used as fingerprints to enable structural determination where databased structures exist, they are generally too complex to fully assign even for relatively simple oligosaccharides (Figure 10a). ^{13}C Spectra are simpler but are also usually too complex to use without the availability of fully assigned NMR spectra from suitable known structures for guidance. The structures of unknown carbohydrates generally demand a variety of through-bond correlated spectroscopy (COSY) and through-space nuclear Overhauser effect spectroscopy (NOESY) 2-D NMR techniques using high field spectrometers (600 MHz) for their elucidation.

Although NMR is an essentially nondestructive method relatively large amounts of material are required and may be lost or degraded if required for long periods. NMR is between three and six orders of magnitude less sensitive than MS. 1-D NMR requires between about 10 nmol (600 MHz) to 80 nmol (300 Mz) and 2-D NMR requires somewhat more. Oligosaccharides have small proton resonance linewidths when compared to proteins which allow 2-D NMR spectra to be obtained at low (~100 μM) concentrations.

^{13}C NMR offers simplified spectra with greater spectral dispersion, which are often best for preliminary information. Complete assignment of ^{1}H NMR and ^{13}C NMR resonances usually starts with the well-resolved anomeric H-1 or C-1 peak using 1-D NMR. The proton resonances can then be assigned sequentially using through-bond techniques;[48] the H-2 by using 2-D time proportional phase incrementation/double quantum filtered/correlation spectroscopy (TPPI/DQF/COSY), then the H-3 using 2-D one-step relayed coherence transfer spectroscopy (RECSY) after eliminating the

Figure 10 ^{1}H NMR spectrum (600 MHz) of the arabinoxylan fragment α-L-Ara*f*-(1 → 2)-β-D-Xyl*p*-(1 → 4)-β-D-Xyl*p*-(1 → 4)-D-Xyl*p*. (a) 1-D NMR showing the distinctive anomeric peaks, mainly as doublets. (b) 2-D HOHAHA NMR showing how off-diagonal assignments of each ring system can be made once the anomeric proton is assigned. Peaks on the diagonal are equivalent to the 1-D NMR spectrum. (Reproduced from *Carbohydr. Res.*, **254**, 245–255, © 1994 by permission from Elsevier Science.)

H-2 signal, followed finally by the H-4 using 2-D time proportional phase incrementation/total correlation spectroscopy (TPPI/TOCSY) after eliminating both the H-2 and H-3 signals. All the protons associated with each carbohydrate residue can be identified using 2-D homonuclear Hartmann–Hahn spectroscopy (HOHAHA), or its close relation, total correlation spectroscopy (TOCSY), in D_2O. The cross-peaks for all ring protons H-2–H-6 (for hexoses) associated with the anomeric proton signal can be distinguished (Figure 10b), as the method utilizes a number of repetitive pulses that permit magnetization to flow freely from one proton to another at a rate determined by their ^3J coupling. TQF/COSY is particularly used to find groups of protons that couple, such as H-4/H-5e/H-5a in pentopyranoses and H-5/H-6/H-6′ in hexopyranoses, but are the most difficult to assign by other correlation techniques. Linkage positions can be found by comparison between related oligosaccharides and noting the field shifts.[49]

The anomeric conformation can often be determined directly from the chemical shift by comparison with known structures. It may be confirmed from the size of the anomeric $^1J_{C-H}$ coupling constant, which is typically 170 Hz for axial hydrogen and 160 Hz if equatorial. The $^3J_{H-H}$ coupling constants obey a Karplus relationship (Equation 12).

$$^3J = A\cos^2(\theta) - B\cos(\theta) + C \qquad (12)$$

A, *B* and *C* are fitted parameters derived from a number of known trainer molecules. The cosine nature of Karplus curves means that it gives one to four possible angles every 360° for a given ^3J (Figure 11). Simple molecular modeling can usually make choice between these as often only one conformation is structurally reasonable. Karplus curves are not exact as other factors, such as bond lengths, bond angles and the nature and orientation of groups attached to the atoms, all have an effect. They can, however, generally give the torsion angles to within about 30° and allow the ring conformation (e.g. pyranose chair conformation $^4C_1$ or $^1C_4$) to be easily verified. Several Karplus parameters are available from different sources, which have been optimized on their

Figure 11 The Karplus relationship $^3J = A\cos^2(\theta) - B\cos(\theta) + C$. For the coupling constants involving the glycosidic linking torsions ($^3J_{COCH}$), *A*, *B* and *C* are 7.6, 1.7 and 1.6 Hz respectively.[58] It can be noted that for any experimental value of ^3J there may be up to four possible torsional angles (e.g. a $^3J_{COCH}$ of 6 Hz may be derived from a torsion of 28°, 131°, 229° or 332°).

own subset of structures or with the aid of quantum mechanical methods. As many compounds often have similar torsional angles for similar structures and a complete range of torsions (0–360°) are rarely available in the model compounds, these parameters may give very different results when away from their training angles. However, even if the parameters are very different, the equation generally gives good correspondence for the commonly found angles. The $^3J_{H-H}$ coupling constants are often able to confirm the molecular species and anomeric configurations present. For example, the anomeric configuration of glucopyranose and galactopyranose are easily observed, from the $^3J_{H1-H2}$ coupling constant, as the H-1 and H-2 protons of the beta anomers are trans-diaxial (~180°) giving large couplings whereas those in alpha anomers are gauche (~60°) with small couplings. Mannopyranose anomers are undecided by this method as both are gauche. D-xylose and D-glucose are characterized by large coupling constants for H-2, H-3, H-4 and H-5 (5a in xylose) arising from their mutually trans-diaxial orientations. Karplus curves giving the relationship of ^3J coupling constants to the H–C–C–H torsion are given in Haasnoot et al.[50]

The power of NMR is most useful when it is used to determine the sequence, linkage positions and conformation of carbohydrates. This can only be attempted when there has been a full assignment of the ^{1}H and ^{13}C spectra and it is preferred that the carbohydrate has been enriched with the ^{13}C isotope. Linkages can be determined from the $^3J_{CH}$ scalar coupling through and across glycosidic bonds using heteronuclear multiple bond correlation (HMBC) and from interglycosidic ^{1}H NOE (nuclear Overhauser effect) effects using NOESY or ROESY (rotating frame nuclear Overhauser effect correlated spectroscopy). This also allows the sequence to be determined from these through-space connectivities. However, with increasing size above about 20 glycosyl residues, it becomes increasingly difficult to delineate branch locations unambiguously. ^{1}H NOE effects give those protons that are in close proximity (less than about 0.5 nm, the signal being inversely proportional to the sixth power of the inter-proton distance). They can be ambiguous particularly at branch points in certain conformations where protons, neighbouring the linkage site, may lie closer than the linkage protons although further apart in the primary structure. NOE effects are also difficult to interpret in the presence of significant internal molecular motion, due to positional averaging. Although NMR is difficulty to apply to many polysaccharides, the presence of repeating units can be identified from the NMR of oligomers and quantified in polymers.

Linkage positions may also be discovered by determination of the position of the free hydroxyl groups, giving information similar to that obtained from methylation analysis (section 5.2), but nondestructively. ^{1}H NMR spectra in H_2O (~10% D_2O) and D_2O are compared to identify the position(s) of the hydroxyl groups.[51] Hydroxyl proton signals are observed, downfield of anomeric protons, in H_2O at low temperature (e.g. −16 °C in H_2O–perdeuterated acetone 4 : 1 v/v) when the pH is adjusted at 6.4 ± 0.2 to reduce the hydroxyl proton exchange with H_2O that is catalyzed above pH 7. Where the hydroxyl protons and their associated C–H aliphatic protons are coupled there is line broadening. If the linewidth comparison fails to give the hydroxyl groups due to overlapping peaks then the COSY CH–OH cross-peaks may be used (in H_2O).

The biological roles of oligosaccharides and polysaccharides are related to their conformations. This mainly depends on the trans-glycosidic torsional angles connecting the carbohydrate units (Scheme 4). Conformational analysis requires independent data for each independent torsion angle (ϕ, ψ and sometimes w) and, where a mixture of conformations exists, each relative population occupancy. These may be available from inter-residue proton NOE (e.g. between the anomeric proton and the proton on the linkage carbon, H–C_1–O–C_n–H) and the $^3J_{COCH}$, $^3J_{COCC}$, $^3J_{CCCH}$ and $^2J_{COC}$ coupling constants (Figure 11) but the cosine nature of the Karplus equation for ^3J coupling means modeling may be required. Whilst the conformation of rigid oligosaccharides can be directly derived from NOESY data, the upper and lower bounds of the possible distances from NOESY often enclose a large number of ϕ, ψ combinations. It is usual to combine NMR, molecular dynamics and random walk molecular mechanics (RAMM) in order to have confidence in the resulting conformation. The additional information available from molecular modeling is particularly useful for polysaccharides where these coupling constants may not be measurable. Modeling is also necessary in oligosaccharides where there are mixed conformational populations present. It should be noted that multiple conformations are often in fast equilibrium on the NMR timescale and NMR data are effectively time-averaged, which may give rise to unrealistic putative torsional angles.

A continuous probability distribution (CUPID) approach can analyze the rotamer populations from NMR spin–spin couplings and NOE enhancements.[52] This gives results reported as typically ±30–40° for the dihedrals and ±0.2 for the probabilities. This method requires an amount of experimental data that is normally only available for rotations around carbon–carbon bonds such as the C5–C6 bond in hexopyranoses.

Solid state ^{13}C NMR has been used on simple highly ordered polysaccharides, such as cellulose, but few detailed conclusions can be drawn.

Scheme 4 The torsions and possible coupling constants involved in the anomeric linkages in oligosaccharides and polysaccharides. (a) Torsions ϕ and ψ are defined as the clockwise torsions $O_rC_aO_aC_n$, and $C_aO_aC_nC_{n-1}$ respectively, where r, a and n represent ring, anomeric and structural number respectively. Alternative torsions are sometimes used as they are easier to determine experimentally; ϕ_H is $H_aC_aO_aC_n$ (about $\phi + 120°$; relative angles are not exact as the bond angles are not exactly tetrahedral) and ψ_H is $C_aO_aC_nH_n$ (about $\psi - 120°$), The relevant coupling constants are $^3J_{H_1C_1OC_4}$ giving ϕ_H, $^3J_{C_1OC_4H_4}$ giving ψ_H, $^3J_{C_1OC_4C_3}$ giving ψ and $^3J_{C_2C_1OC_4}$. (b) An exocyclic link; the additional linking torsion w is defined as the clockwise torsion $O_aC_nC_{n-1}C_{n-2}$. The relevant coupling constants are $^3J_{H_1C_1OC_6}$ giving ϕ_H, $^3J_{C_1OC_6C_5}$ giving ψ, $^3J_{C_1OC_6H_{6'1}}$, $^3J_{C_1OC_6H_{6'2}}$, $^3J_{C_2C_1OC_6}$, $^3J_{H_{6'1}C_6C_5C_4}$ and $^3J_{H_{6'2}C_6C_5C_4}$.

7.3 Infrared Spectroscopy

Fourier transform infrared (FTIR) is a rapid non-destructive and quantitative method for determining oligosaccharides and polysaccharides. Pure samples of the glycans and any interfering substances must be available for comparison. FTIR determines the whole spectrum at once, easily allowing a number of scans to be averaged to achieve high sensitivity and resolution. The complexity of the spectra means that it is not suitable for totally unknown mixtures where there may be interference from unknown materials.[53] Analysis is achieved from the absorbance at a number of differing wavelengths ($\sim$900–1200 cm^{-1}, e.g. the C–O stretching vibration) after comparison with the absorbance matrix obtained using the calibration materials.

LIST OF SYMBOLS

A_2	Second Virial Coefficient
c	Sample Concentration
D	Diffusion Coefficient
J	Coupling Constant
K	Optical Parameter
M	Molecular Weight
M_n	Number-averaged Molecular Weight
M_w	Weight-averaged Molecular Weight
$\overline{M}_w$	Mean Weight-averaged Molecular Weight
m/z	Mass to Charge Ratio
n	Refractive Index
N_A	Avogadro's Number
R	Gas Constant
R_θ	Excess Intensity of Scattered Light at Angle θ
R_f	Movement of a Solute Relative to the Solvent Front
R_G	Radius of Gyration
s	Sedimentation coefficient
T	Temperature

ABBREVIATIONS AND ACRONYMS

ACN	Acetonitrile
CE	Capillary Electrophoresis
CID	Collision-induced Dissociation
CID/FTMS	Collision-induced Dissociation/ Fourier Transform Mass Spectrometry
COSY	Correlated Spectroscopy
CUPID	Continuous Probability Distribution
CZE	Capillary Zone Electrophoresis
DEAE	Diethylaminoethyl
DHB	2,5-Dihydroxybenzoic Acid
DMSO	Dimethyl Sulfoxide
DP	Degree of Polymerization
EI/MS	Electron Impact/Mass Spectrometry
ESI	Electrospray Ionization
FAB	Fast Atom Bombardment
FAB/MS	Fast Atom Bombardment/Mass Spectrometry
FTIR	Fourier Transform Infrared
GC	Gas Chromatography
HILIC	Hydrophilic Interaction Chromatography
HMBC	Heteronuclear Multiple Bond Correlation
HOHAHA	Homonuclear Hartmann–Hahn Spectroscopy
HPAEC	High-performance Anion-exchange Chromatography Methods
HPAEC/PAD	High-performance Anion-exchange Chromatography coupled with Pulsed Amperometric Detection
HPLC	High-performance Liquid Chromatography
HPSEC	High-performance Size Exclusion Chromatography

HPTLC	High-performance Thin-layer Chromatography
LALLS	Low-angle Laser Light Scattering
LS	Light Scattering
MALDI	Matrix Assisted Laser Desorption Ionization
MALLS	Multiangle Laser Light Scattering
MS	Mass Spectrometry
MS/MS	Tandem Mass Spectrometry
NMR	Nuclear Magnetic Resonance
NOE	Nuclear Overhauser Effect
NOESY	Nuclear Overhauser Effect Spectroscopy
ODS	Octadecylsilane
PAD	Pulsed Amperometric Detection
PMP	1-Phenyl-3-Methyl-5-Pyrazolone
PSD	Post-source Decay
RAMM	Random Walk Molecular Mechanics
RECSY	Relayed Coherence Transfer Spectroscopy
RI	Refractive Index
ROESY	Rotating Frame Nuclear Overhauser Effect Correlated Spectroscopy
SDS/PAGE	Sodium Dodecyl Sulfate/ Polyacrylamide Gel Electrophoresis
S-DVB	Sulfonated Styrene Divinyl Benzene
SEC	Size Exclusion Chromatography
S-PS	Sulfonated Polystyrene
TLC	Thin-layer Chromatography
TOCSY	Total Correlation Spectroscopy
TOF	Time-of-flight
TPPI/DQF/COSY	Time Proportional Phase Incrementation/Double Quantum Filtered/Correlation Spectroscopy
TPPI/TOCSY	Time Proportional Phase Incrementation/Total Correlation Spectroscopy
UV	Ultraviolet
VA	Vinyl Alcohol

Glycolipids are conjugated macromolecules that have a carbohydrate (oligosaccharide) component covalently bound to a lipid (diacylglycerol, ceramide, sterol or polyprenol) component. They are present both in procaryotes and eucaryotes but the carbohydrate components, as well as the lipid components, vary considerably between different animal, plant and microbial cells. The biological specificity of a glycolipid is due mainly to the carbohydrate structure. The amphipathic nature of glycolipids means that a single extraction scheme is impractical for all the different molecular species while special techniques are required to differentiate between the neutral glycolipids and acidic glycolipids (gangliosides). Thin-layer chromatography (TLC) and high-performance liquid chromatography (HPLC) are the major purification methods. Chemical methods are used to determine the carbohydrate and lipid profiles as well as the linkage analysis of both types of components and are used in conjunction with gas chromatography (GC), HPLC and TLC, sometimes coupled with mass spectroscopy (MS). Enzymatic methods can be used to determine the linkage sequence and anomeric configurations of the oligosaccharide structures and the same parameters are being determined by immunological methods with increasing frequency. Enzymatic methods are also used to establish the linkage analysis of the fatty acid in the diacylglycerol species. However, various MS and both ^{1}H- and ^{13}C-NMR (nuclear magnetic resonance) methods, but mostly the former, are now invariably used to confirm the full structural features of an unknown glycolipid. The type of MS method used, matrix-assisted laser desorption/ionization (MALDI), fast atom bombardment (FAB) or tandem mass spectrometry (MS/MS) will depend on the type of glycolipid.

1 INTRODUCTION

Glycoconjugate is the general term applied to macromolecules, usually biological, that have a carbohydrate component covalently bound to a noncarbohydrate component. The most widespread examples are glycoproteins and glycolipids. The same complex carbohydrate component can be associated with both examples. Glycolipids are found both in procaryotes and eucaryotes but the complex carbohydrate components, as well as the compounds that are considered to be the lipid components, vary considerably between the different animal, plant and microbial cells. Some simple glycolipids have been synthesized on an industrial scale and have commercial applications. The glyco components are complex oligosaccharide chains that may involve frequent branching. The carbohydrate components can also carry noncarbohydrate substituents such as acetate or sulfate groups linked by covalent chemical bonds. The lipid component is far more variable since many types of compound are considered as lipids. Diacylglycerol, ceramides (amides derived from a fatty acid and a sphingosine base), sterols and polyprenols are the most abundant. The biological specificity of a glycolipid is due more to the overall carbohydrate structure and influenced less by the lipid component.

In glycoglycerolipids, glycerol is always in the *sn* configuration and fatty acids are attached at C-1 (*sn*-1) and C-2 (*sn*-2) by ester bonds: it is unusual for the same

Figure 1 General structure of (a) a D-galactosyldiacylglyceride and (b) and (c) the two related disialogangliosides, G_{D1a} and G_{D1b}, respectively.

fatty acid to occupy both positions. The carbohydrate components, mostly frequently D-galactose or oligomers of this sugar residue, are always joined at C-3 (*sn*-3) by a glycosidic bond. A D-galactosyldiacylglyceride is shown in Figure 1(a). For the cerebrosides, the sphingosine base is normally unsaturated and its primary hydroxy group is involved in a glycosidic bond with the reducing end of the carbohydrate chain. The disialogangliosides G_{D1a} and G_{D1b} are shown in Figures 1(b) and 1(c). The cerebrosides can be subdivided into neutral cerebrosides and acidic cerebrosides (gangliosides). The neutral cerebrosides contain mainly neutral hexose and hexosamine residues while the gangliosides are characterized by the presence of the nine-carbon sugar, neuraminic acid, as well as the same sugars as are found in the neutral cerebrosides. Sulfatides are a special form of cerebrosides containing sulfate ester groups. As more sensitive detection methods are used, the range and complexity of carbohydrates present in glycolipids is increasing. D-Galactose has been found in the more unusual furanose form while residues of the acidic sugar, D-glucuronic acid, have also been detected. *N*-Acetylneuraminic acid is not the only sialic acid, *N*-glycolyl and N-O-disubstituted derivatives now being frequently detected, while other sugars, such as 3-deoxy-D-*glycero*-D-*galacto*-2-nonulosonic acid (KDN), are no longer considered to be rare. Molecular species can be found from the same source which have the same oligosaccharide chain along with the same sphingenine base but have different fatty acids present. The linkage between sterols and the carbohydrate chains are also through glycosidic bonds. The polyprenol-types are unique amongst the glycolipids as the link is via a phosphate bridge. Sterol- and polyprenol-types are not present in tissues and cells at high concentrations but the latter are widespread, being involved as transporters for the carbohydrate components of biologically active molecules.

2 EXTRACTION AND PURIFICATION

The very nature and definition of the name 'glycolipid' confirms that care must be taken during isolation and purification. Although carbohydrates are frequently, although not exclusively, water-soluble, the high concentration of hydroxy groups in their structures makes them hydrophilic. In contrast, lipids, by definition, are water-insoluble organic substances that can be extracted with nonpolar solvents. All glycolipids are, therefore, amphipathic. The combination of hydrophilic and hydrophobic regions in the same molecule accounts for many of their biological functions, especially in membranes, but does make their isolation and characterization more difficult.

The amphipathic nature means that the solvent system will generally require a polar and a nonpolar component. However, as the percentage of polar component to nonpolar component in a specific glycolipid (or lipoglycan) will depend on its composition and could approach either 0% or 100%, the ideal solvent system for any particular glycolipid needs to have similar polarity. No single solvent or mixture of solvents will, therefore, be capable of extracting all the glycolipids from a single biological sample.

Another paramount consideration when isolating glycolipids is the lability of the glycolipid in the extracting or purification solvent. The different covalent bonds in glycolipids have different labilities under acidic and alkaline

conditions. Glycosidic bonds between the sugar residues in the oligosaccharide component as well as to the lipid component are relatively stable under alkaline conditions but are cleaved in acidic conditions, especially at elevated temperatures. All glycosidic bonds are not equally labile in acid and this factor can be used in structural analyses. Other components, particularly esters substituents, are less stable in alkaline conditions than acidic conditions. Unless some structural information has been previously obtained, both acidic and alkaline conditions should be avoided during extraction. Enzymic hydrolysis may also occur if precautions are not taken. Before biological samples are extracted, enzymes, if present, need to be inactivated. This is particularly relevant for the plant glycolipids since phospholipases and galactolipases may be present. Under these circumstances, a prior treatment with boiling propan-1-ol is recommended.[1] Furthermore, care needs to be taken to prevent oxidation of unsaturated fatty acids as well as to minimize the co-extraction of plant pigments that can interfere with subsequent fractionation.

2.1 Extraction

Even though animal glycolipids are mainly glycosphingolipids and plant glycolipids are mainly monoglycosyldiacylglycerols, most of the extraction procedures are based on the related methods of Folch et al.[2] and Bligh and Dyer[3] that were published in the late 1950s. Both procedures recommend that the fresh tissue is extracted with a chloroform–methanol mixture for up to 1 h at temperatures from 4° to 25 °C (sometimes up to 100 °C is reported), with 4 °C being preferred. Temperatures above ca. 25 °C ought to be avoided unless labile constituents are known to be absent. Extraction periods as low as 3 min have been used. Periods of over 1 h are only recommended when fresh material is not available and lyophilized samples have to be used.

The recommended chloroform–methanol ratio depends on the proportions of lipid to carbohydrate in the glycolipid. Ratios from 1:2 through 1:1 to 2:1 have all been published and many authors cite sequential extractions with the different ratios. When a suspension of fresh tissue is used at a ratio of 3.75 volumes solvent to 1 volume tissue, the chloroform–methanol (1:2 v/v) mixture gives a one-phase extract containing chloroform–methanol–water (1:2:0.8 v/v/v). On adding more water and chloroform, two phases are produced with the glycolipids being found in the lower chloroform-rich phase and the nonlipid components being partitioned into the upper water-rich phase. The chloroform-rich phase is dried under vacuum and should be immediately fractionated or, if this is not practical, stored in a water-free form in chloroform–methanol (2:1) at −20 °C. When an unknown source has being extracted, the water-rich phase should be examined to see if any highly polar glycolipids are present in that fraction. Clearly, even using chloroform : methanol mixtures, there is no single procedure that can be recommended for the extraction of all glycolipids from every biological source and, ideally, the method that is used requires optimization for the source being investigated.

Alternative solvent systems have been proposed. When chloroform–methanol (1:2) is used, 0.4 M sodium acetate can been used instead of water and is reported to give improved results when gangliosides are present.[4] Another method, also reported to be particularly applicable to gangliosides, uses 0.01 M phosphate buffer in tetrahydrofuran.[5] For the extraction of higher plant glycolipids, fresh tissue is fragmented in dry ice and homogenized in boiling propan-2-ol for 1–2 min. This procedure is recommended when degradative enzymes may be present. It is also reported to minimize peroxidation.

2.2 General Purification

In parallel with the extraction of glycolipids, no single method can be used to separate all the glycolipids in an extract from co-extracted contaminants. Each procedure must be tested for the particular fraction required. When the chloroform–methanol extracts obtained from either the Folch et al.[2] or Bligh and Dyer[3] procedures are separated into a two-phase system, the lower phase contains the neutral glycolipids, particularly those with short carbohydrate chains, as well as neutral lipids and phospholipids, while the upper phase contains not only the gangliosides and the neutral glycolipids with longer carbohydrate chains but also contaminating glycoproteins and glycopeptides. When gangliosides are present, the water-rich upper layer can be dialyzed against distilled water at 4 °C for 2–3 days and the ganglioside fraction recovered by lyophilization of the retentate.

Many procedures have been published for general purification ranging from precipitation with propan-2-one to countercurrent distribution but the vast majority of applications use column chromatography. While diethylaminoethyl (DEAE) matrices have been used in the chromatographic methods, most procedures use silica gel when significant quantities of material are available. After applying the crude extract, such as the lower phase from a chloroform–methanol extract, to the column, neutral lipids and pigments are eluted by washing with chloroform and the glycolipids can be eluted by washing with chloroform–propan-2-one (1:1 v/v) or propan-2-one alone. Gradient elution can be used to provide an initial fractionation. Phospholipids, if present, can be recovered by subsequent elution with methanol–chloroform.

An adaptation of this procedure, initially described for gangliosides, was proposed by Williams and McCluer,[6] who used solid phase extraction (SPE) columns packed with a matrix containing bonded octadecylsilyl (ODS) groups. These cartridge columns (Sep-Pak™) are loaded with the ganglioside mixture present in the water-rich upper layer from a chloroform–methanol extract. Washing with water, under slight either positive or negative pressure, removes the ions, and the gangliosides are removed by washing with methanol or chloroform–methanol.

As well as ODS-bonded matrices, cartridges are now available with a range of matrices such as silica gel as well as both cation- and anion-exchange materials. Being produced under standard commercial conditions, the reproducibility between columns can almost be guaranteed. With care and suitable washing, the cartridges can be used a number of times. The use of SPE in all aspects of lipid analysis has been reviewed.[7] Gel permeation matrices have also been used for general purification procedures. The water-compatible Sephadex G-25[8] and the matrix designed for nonaqueous solvents, Sephadex LH-20,[9] have both been used.

2.3 Separation into Neutral Glycolipid and Acidic Glycolipid (Ganglioside) Fractions

The ability of the acidic sugar residue(s) in the ganglioside to bind to DEAE-groups attached to various supports is the main method and a procedure[10] using DEAE–Sephadex is typical. The authors recommend that the acetate form of the gel and the column be prewashed with chloroform–methanol–water (15 : 30 : 4 v/v/v) before loading the sample in the same solvent mixture. The neutral glycolipids are washed off using the same solvent and the gangliosides are then eluted with 0.8 M sodium acetate in methanol.

Since individual gangliosides may contain more than one acidic (sialic acid) residue, DEAE-matrices can also be used to fractionate mono-, di- and trisialoganglioside mixtures.[11] This procedure recommends that the crude ganglioside mixture is dispersed in chloroform–methanol (1 : 1) and mixed with the acetate form of DEAE–Sephadex A-25 with shaking. The suspension is diluted with methanol–water (15 : 4 v/v) before being packed into the column. The neutral lipids are eluted with chloroform–methanol–water (15 : 30 : 4 v/v/v) and neutral glycolipids with methanol. The gangliosides can then be fractionated using a concave gradient of 0–0.45 M ammonium acetate in methanol. Ganglioside species containing a single sialic acid residue are eluted first and those with 3–4 residues require the higher molarity of ammonium acetate.

2.4 Separation of Glycolipid Mixtures

2.4.1 Thin-layer Chromatographic Methods

TLC procedures for lipid separations have been reviewed[12] and their applications in glycolipid analyses are numerous. Using the term high-performance thin-layer chromatography (HPTLC) as a special form of this technique highlights the availability and reproducible quality of very fine grade silica gels. It has many advantages over HPLC. The fineness results in superior resolution. These grades of silica gel cannot be used in HPLC due to the pressure requirements, while very sensitive but destructive or corrosive reagents can be used for detection purposes. The plates are readily impregnated with additives such as Ag^+ or borate ions that enhance the separation of specific components such as unsaturated or vicinal dihydroxy-containing compounds.

Neutral solvent systems, such as chloroform–methanol–water (65 : 25 : 4 v/v/v), are recommended for neutral glycolipids. Derivatization of the glycolipid by, for example, acetylation is not reported to give any improvement to the separation. Any acceptable reagent that can detect nonreducing sugars, such as orcinol/H_2SO_4, can be used to visualize the components. When carrying out preparative TLC, care should be taken to prevent the plates drying out: quantitative recovery is not achieved even when ultrasonic treatment is used.

The best methods for the separation of gangliosides are also based on silica gel and detection is achieved with the resorcinol/HCl spray reagent. However, a basic solvent system (e.g. chloroform–methanol–water–ammonia (60 : 35 : 7 : 1 v/v/v/v)), or one containing Ca^{2+} ions (e.g. chloroform–methanol–0.2% aqueous $CaCl_2$ (60 : 40 : 9 v/v/v)) gives optimum separations in a one-dimensional system.[13]

Two-dimensional (2-D)/TLC is frequently used for analyzing glycolipid mixtures, particularly when only small quantities of material are available (see, for example, Sonnino et al.).[14] For neutral glycolipids, chloroform–methanol–0.2% $CaCl_2$ (60 : 35 : 8 v/v/v) has been recommended for both dimensions while for ganglioside molecular species, chloroform–methanol–0.2% $CaCl_2$ (55 : 45 : 10 v/v/v) has been recommended for the first dimension and propan-1-ol–water–25% NH_4OH (75 : 25 : 5 v/v/v) for the second.

A simple and quantitative purification procedure, based on TLC, is termed TLC blotting.[15] After 2-D HPTLC, the separated components are treated with primuline and visualized under ultraviolet (UV) light. The bands are marked with a colored drawing pencil then transferred, by TLC blotting, onto a polyvinylidene difluoride (PVDF) membrane. The major advantage is the yield and purity of the products. Direct extraction of an HPTLC plate rarely recovers more than 50% of the

lipid component while yields of 80–90% are regularly achieved using the PVDF membrane. Another benefit of PVDF membrane technology is the development of more sensitive detection methods. When the glycolipids on the PVDF membrane are mildly oxidized, they can be conjugated with streptavidin–horseradish peroxidase and, using enhanced chemiluminescence, are clearly visible at a concentration factor of 10 lower than detected by the orcinol reagent.[16] The method can be generally applied to the use of a specific antibody for detection and, since the staining procedure is nondestructive, the glycolipids can still be used for further molecular analyses.

A further adaptation of 2-D TLC, especially applicable to gangliosides, is termed TLC mapping.[17] The glycolipid mixture is first chromatographed in one dimension on a narrow NH_2-silica gel HPTLC strip using chloroform–methanol–1% diethylamine (50 : 47 : 15 v/v/v). This strip is then clamped to a 2-D TLC plate and developed with chloroform–methanol–25% NH_4OH (4 : 10 : 6 v/v/v). The partially separated glycolipids are transferred from the strip to the plate and chromatographed in the first dimension in a simultaneous process. The plate can then be run in the second dimension with chloroform–methanol–0.2% $CaCl_2$ as above. The method allows the determination of membrane constituents, particularly those that are present at low concentrations. A typical TLC map of the gangliosides from rat brain is shown in Figure 2.

2.4.2 High-Performance Liquid Chromatographic Methods

Because of the expansion in the use of HPTLC (see section 2.4.1), the applications using HPLC have not expanded as greatly as anticipated a decade ago. Columns that can compete with HPTLC by incorporating Ag^+ and borate ions have been developed and gradient elution at different temperatures is easy to perform. However, the pressure limits on the fineness of the silica gel that can be used as well as the detection limits are major obstacles. The IR detector is too insensitive while UV detection at 190–210 nm is nonspecific.

For native glycolipids, HPLC on silica is used for the separation of lipid classes while reversed-phase or bonded columns are used for the separation of molecular species.[18] Native neutral glycolipids can be separated on porous silica using a gradient involving propan-2-ol–hexane–water. For native gangliosides, silica gel and DEAE-linked glass beads have been used but the preferred method uses Lichrosorb-NH_2 or μ-Bondapak-NH_2 columns. Molecular species within mono-, di- and trisialoganglioside fractions can be separated on a single run.[19]

The introduction through chemical modification of the more UV-sensitive benzoyl or *p*-nitrobenzoyl groups into the glycolipids has greatly reduced the sensitivity problem. These groups also change the polarity of the glycolipid and allow a widely different set of solvent systems to be used. While the *p*-nitrobenzoyl derivatives are more UV-sensitive, the benzoyl derivatives usually give a better separation. The method used to prepare the derivatives is also important and depends on whether the native glycolipid needs to be recovered intact. Benzoyl chloride in pyridine gives a fully substituted product but treatment with benzoic anhydride and 4-dimethylaminopyridine as catalyst results only in O-benzoylation. The fully benzoylated derivative gives better separations than the O-benzoylated product. However, attempts to recover the

Figure 2 2-D thin layer chromatogram (TLC map) of the ganglioside mixture isolated from rat brain:[17] (a) to (d) refer to the mono- to tetrasialoganglioside fractions, respectively, and (e) refers to an, as yet, unidentified ganglioside fraction. (Reprinted with permission of Academic Press, New York from *Anal. Biochem.*, **227**, 195–200 (1995).)

native glycolipid with mild alkali only remove *O*-benzoyl groups: the *N*-benzoyl groups on either the sphingosine base or any amino sugars are stable.[20]

More recent developments with moving wire flame ionization detectors offer increased sensitivity for native glycolipids and the evaporative light-scattering detector is also a sensitive detection method when separating lipid classes, including glycolipids. This latter technique has been used to separate the nine phospho- and glycolipid classes present in plant membranes.[21]

2.4.3 Supercritical Fluid Chromatographic Methods

SFC is a relatively new technique that has been adapted by Reinhold et al.[22] for the separation of glycolipids. In general, thermally labile and nonvolatile compounds can be analyzed at lower temperatures than are possible with GC while the use of a flame ionization detector gives the method increased sensitivity over HPLC. A permethylated ganglioside mixture containing the mono-, di- and trisialogangliosides, G_{M1}, $G_{D1a,b}$ and G_{T1b}, has been separated on an SB-phenyl-5™ column at 120 °C using CO_2 as the supercritical fluid. The separation is shown in Figure 3. Possibly the main strength of the method is the ability to couple directly to a mass spectrometer and use the CO_2 along with NH_3 as chemical ionization reagent (see section 5.1).

2.4.4 Capillary and Thin-layer Electrophoretic Methods

These techniques have mainly been applied to the carbohydrate components released from glycoconjugates in general. The capillary and thin layer electrophoresis of both underivatized and derivatized carbohydrates have been reviewed by Oefner and Scherz,[23] while Jackson[24] has reviewed the high-resolution polyacrylamide gel electrophoresis of fluorophore-labeled carbohydrates. Gangliosides have been separated by capillary zone electrophoresis using cyclodextrin.[25]

3 CHEMICAL METHODS OF ANALYSIS

3.1 Composition of Glycolipids

3.1.1 Carbohydrate Profiles

The glycosidic bonds present in any polymeric carbohydrate, including glycolipids, are hydrolyzed under acidic conditions. Hydrolysis is most efficient when carried out under homogeneous conditions but the amphipathic nature of all glycolipids means that a single process cannot be recommended for all glycolipids. Glyolipids with a high proportion of carbohydrate residues are more likely to be soluble in an aqueous acidic solution while those with a small proportion of carbohydrate residues require

Figure 3 Supercritical fluid chromatography (SFC) mass spectrometry of the permethylated gangliosides G_{M1}, $G_{D1a,b}$ and G_{T1b} from bovine brain using NH_3/CO_2 as CI reagent gas.[22] (Reprinted with permission of Academic Press, New York from *Anal. Biochem.*, **193**, 24–34 (1991).)

a less polar solvent such as an acidic water–methanol mixture.

Furthermore, the glycosidic bonds of each type of carbohydrate residue found in glycolipids are not hydrolyzed at the same rate. In general, those involving amino sugars (e.g. galactosamine and its naturally occurring *N*-acetyl derivative) are relatively stable and require high concentrations of H^+ ions (ca. 0.3 M) for longer periods of time and at elevated temperatures. Glycosidic bonds involving the pyranose forms of most hexoses (e.g. gluco- and galactopyranose) are less stable. They still require high concentrations of H^+ ions (ca. 0.3 M) at elevated temperatures but not for such long periods. The precise conditions will depend on the sugar residue, its ring size (pyranose or furanose), its anomeric configuration (α or β) and the position of linkage to the aglycone. The aglycone can be another sugar residue, the sphingosine base, glycerol or whatever the lipid is. The most labile sugar residues found in glycolipids are the sialic acids or any furanosyl forms of sugars. In particular, galactofuranosyl groups have been identified in glycolipids from many microbiological sources.

In practice, it is not possible simply to use the conditions required to hydrolyze the most stable glycosidic bond. The reducing sugars released by hydrolysis are themselves unstable when exposed for prolonged periods to acidic conditions at elevated temperatures. The sialic acids present in gangliosides are particularly unstable. It must also be remembered that noncarbohydrate substituents attached to sugar residues, such as the *N*-acetyl groups on amino sugars and acetyl or sulfate groups present on neutral sugar residues, will also be hydrolyzed under acidic conditions. Preliminary analyses may be necessary to select the optimum conditions for a particular glycolipid.

Hydrolysis procedures involving H_2SO_4, HCl and trifluoracetic acid have been recommended but one using glacial acetic acid–0.15 M H_2SO_4 (9 : 1) at 80 °C for 6 h is frequently used. After neutralization of the H^+ or removal via an ion-exchange resin, the dried hydrolysate is reduced with borohydride to the corresponding alditol. Borodeuteride is used if subsequent analysis will include mass spectrometry. This procedure simplifies the chromatography by converting the α/β anomers of the pyranose/furanose forms into a single product. The alditol is then acetylated with acetic anhydride and products analyzed by GC or GC/MS. Many variations have been published but the general procedure of Watanabe et al.[26] is recommended. Improved gas chromatographic procedures have been published (see, for example, Blakeney et al.)[27] and milder acetylation conditions involving the use of 1-methylimidazole as catalyst[28] have been recommended. These hydrolysis conditions are necessary to release amino sugars but sialic acid residues are destroyed.

Methanolysis is recommended for gangliosides but can be used for other glycolipids. The glycolipid is treated with 1.0 M methanolic HCl at 85 °C for 18 h in a sealed tube. This procedure hydrolyzes the glycosidic bonds but simultaneously protects the vulnerable hemiacetal group by creating the methyl glycosides. After neutralization with Ag_2CO_3 or ion-exchange resin, and re-N-acetylation if amino sugars are present, the trimethylsilyl (TMS) derivatives of the methyl glycosides are prepared by conventional methods[29] and analyzed by GC.[30] The methanolysis procedure is acceptable for terminally-linked sialic acids but the conditions need to be made less severe when internal sialic acid residues are present. Since sialic (neuraminic) acid residues can be present carrying either *N*-acetyl or *N*-glycolyl substituents, as well as some residues being disubstituted, specific procedures involving GC, HPLC or colorimetric analyses have been reviewed.[31]

An interesting scheme has been proposed by Wiesner and Sweeley[32] where the glycolipid is methanolyzed with 0.75 M HCl in methanol. Using a glycolipid that contained a sialic acid residue and an amino sugar as well as neutral sugars, methanolysis was complete in 2 h at 110 °C. Instead of the TMS derivative, peracetylation introduced the more stable acetyl group. In contrast to other procedures, the individual sugar residues, the fatty acids and the sphingosine moieties could all be determined by a single GC separation in 45 min. This procedure is likely to be universally adopted.

The carbohydrate profiles from the plant monoglycosyldiacylglycerols are now known to be more complex than originally reported. In addition to the three carbohydrate moieties, β-D-galactopyranosyl, 6′-*O*-α-D-galactopyranosyl-β-D-galactopyranosyl and sulfoquinovosyl frequently cited, higher homologues of the second have been found as well as all β and mixed α/β linked galactosyl oligosaccharides.

3.1.2 Fatty Acid Profiles

The release of the individual fatty acids present in glycolipids is subject to the same general problems that were discussed for the carbohydrate profiles (see section 3.1.1). A purely aqueous hydrolysis is not practical and the most generally recommended method involves heating a methanol–H_2O–conc HCl (29 : 4 : 3) mixture at 80 °C for 18 h in a sealed tube under N_2. After extraction of the fatty acids (and some methyl esters), all the fatty acids are esterified with 1.5 M methanolic HCl and determined by capillary GC on a BP1 or BPX70 column.[33]

Methyl esters have been prepared using different reagents such as BF_3/methanol, $AlCl_3$/methanol and diazomethane. Pentafluorobenzyl esters have significant advantages if the more-sensitive electron capture detector is used for the GC whereas propan-2-yl esters give better

resolution for the different *trans* isomers. If the analysis involves GC/MS, the introduction of an N-containing ester group, such as a picolinyl or pyrrolidide group, is preferred for the MS.[34] When hydroxy fatty acids are present, the peak width of these acids is increased and tailing also occurs. The quality of the chromatograms and, therefore, the accuracy of quantification are improved by trimethylsilylating the hydroxy groups of the fatty acid methyl esters. The retention times are also reduced.

Reversed-phase HPLC offers an alternative strategy for the analysis of individual fatty acids and the topic has been reviewed.[35] The methyl esters are not sufficiently sensitive for most HPLC detection systems but the introduction of a phenacyl group allows more sensitive detection in the UV while introduction of the 4-bromomethyl-7-methoxycoumarin group allows detection by fluorescence. Ag^+ ion chromatography has special benefits when double bonds are present and the presence of borate ions assists the separation of any dihydroxy acids.

3.1.3 Other Components

The sphingosine bases are released from glycosphingolipids by treatment with methanol–H_2O–conc HCl (29 : 4 : 3 v/v/v) as described above for the release of fatty acids (see section 3.1.2). They remain in the acidic aqueous phase when the fatty acids and esters are extracted with petroleum ether but can then be extracted with diethyl ether when the pH is raised to >8. They are then determined by GC of their TMS derivatives[36] but the scheme proposed by Wiesner and Sweeley[32] for carbohydrate profiles (see section 3.1.1) can be used to determine the sphingosine bases simultaneously.

Sterols are released and isolated by a similar method to the sphingosine bases. They can be analyzed directly by GC but the acetate derivatives give improved resolution and analysis times. Glycerol is quantitatively released from plant glycolipids by the action of $LiAlH_4$ in diethyl ether. After purification, the glycerol content can be determined, without derivatization, by GC. It can also be determined spectrophotometrically[37] using the enzymes pyruvate kinase, lactate dehydrogenase and glycerokinase with appropriate cofactors.

3.2 Linkage Analysis of Carbohydrate Chains

Linkage analysis of the carbohydrate chain in a glycolipid will not give an unambiguous structure of the carbohydrate component of a glycolipid. It will give an indication of the relative position of each sugar residue present and, by analogy with known structures, the unknown structure may be derived. All nonreducing terminal residues are identified as well as main chain residues that have a single substitution point and branch points that are doubly substituted. The pattern is mainly determined after permethylation of the glycolipid (or the oligosaccharide derived from it). The product is then hydrolyzed to the partially methylated sugars, reduced, acetylated and the products determined by GC or GC/MS. The essential requirement is that every hydroxy group must be substituted. This may not always occur for native glycolipids; under these circumstances, it is preferable to release the oligosaccharide chain prior to methylation.

3.2.1 Isolation of Oligosaccharide Chains

A number of procedures have been used to isolate intact oligosaccharide chains from native glycolipids. Most rely on the presence of a double bond in most naturally occurring sphingosine bases. In the procedure using osmium tetroxide/periodic acid,[38] the glycolipid is first acetylated before the oxidizing agents break the double bond in the sphingosine base. The rump of the base is finally removed from the oligosaccharide chain with sodium methoxide, which also removes the acetyl-protecting groups to leave the intact oligosaccharide. Recoveries are not complete: the recovery from a ceramide with three sugar residues was 70% but <50% from a ceramide with two sugar residues. Ozone can also be used to split the unsaturated bond in the sphingosine base without the need to acetylate and the aldehydic rump is removed with aqueous base.

Trifluoroacetolysis results in different products depending on the ratio of trifluoroacetic acid to trifluoroacetic anhydride.[39] O-trifluoroacetylation is complete and amino functions are all N-trifluoroacetylated. *N*-Acetyl groups undergo transamidation to *N*-trifluoroacetyl groups but sialic acid residues are hydrolyzed from the gangliosides. If an unsaturated sphingosine base is present, the oligosaccharide is released, although yields are not quantitative. A 1 : 1 ratio is recommended for monoglycosylceramides, giving a better yield of glucose or galactose, while a 1 : 50 ratio gave a better yield with a triglycosylceramide.

3.2.2 Methylation Procedures

The ability to methylate oligosaccharide chains fully in intact glycolipids or those released from glycolipids (see section 3.2.1) with essentially no degradation is based on the work of Hakomori.[40] The method uses the methylsulfinyl anion, generated from NaH and dimethylsulfoxide (DMSO), to ionize all the hydroxy groups on a carbohydrate and these are converted to methyl ethers by reacting with iodomethane. Over the years, many modifications have been suggested, including a cleaner preparation of the methylsulfinyl anion from KH or potassium *t*-butoxide. The hazardous nature of the preparation of these carbanions, particularly that

prepared from KH, needs to be stressed. Although relatively stable as dispersions in mineral oil, pure hydrides are extremely reactive and must only be used in small quantities and with great care.

As for the carbohydrate profiles (see section 3.1.1), the composition of the carbohydrate component of the glycolipid, and therefore the stability of the individual glycosidic linkages, will affect the hydrolysis conditions employed to depolymerize the permethylated glycolipid. If amino sugars are present, stronger hydrolysis conditions are needed such as glacial acetic acid–5 M H_2SO_4 (19 : 1 v/v) at 80 °C for 18 h. When only neutral sugars (or sialic acids) are present, permethylated glycolipids can be depolymerized by heating with 95% formic acid at 100 °C for 2 h. Conventional methods are used to clean up the products. 2 M Trifluoroacetic acid at 121 °C for 1 h is a convenient alternative when only neutral sugars are present: the acid can be conveniently removed in a stream of N_2.

Most applications use GC or GC/MS to identify and quantify the products and the alditol acetate method is that of choice (see section 3.1.1). The procedure has been reviewed.[41] A more recent advance has been selectively to hydrolyze the permethylated glycolipid at a labile bond. In this procedure, the oligosaccharides released are reduced, the generated hydroxy groups are converted to ethyl ethers (as for methylation) and products separated by HPLC. GC/MS or MS alone allows structural features of the oligosaccharides to be determined.

3.3 Anomeric Configuration of Carbohydrate Residues

There are no chemical methods currently available that will definitively identify the anomeric configurations of the carbohydrate residues in a glycolipid, and biochemical and/or physical methods (see sections 4 and 5) are far more reliable.

3.4 Linkage Analysis of Fatty Acids

In plant glycoglycerolipids, as well as variations in the structures of the carbohydrate components (see section 3.1.1), the fatty acids esterified to the glycerol backbone can vary. The structure, isolation and analysis of plant glycolipids have been reviewed.[42] Irrespective of the nature of the carbohydrate, it is always attached to C-3 of glycerol in the *sn* configuration. The fatty acids, therefore, are attached to C-1 and C-2 and the overall pattern as well as the distribution of individual fatty acids in each molecular species is biologically and industrially important.

Lipases have been isolated from a number of sources that are regioselective for the *sn*-1 ester group and so are capable of releasing the intact acyl group from C-1 (*sn*-1) of all glycoglycerolipids except those containing sulfoquinovosyl groups. This fatty acid can be directly determined (see section 3.1.2) and the lysoglycolipid, which still contains the acyl group attached to C-2 (*sn*-2) can then be hydrolyzed and this fatty acid also determined. Only one extracellular lipase, isolated from *Rhizopus arrhizus*, is capable of carrying out the above reaction with the sulfoquinovosyl-containing glycoglycerolipids.

4 BIOCHEMICAL METHODS OF ANALYSIS

4.1 Linkage Analysis and Anomeric Configuration via Specific Glycosidases

Exo-glycosidases act by cleaving the glycosidic bond of that specific glycoside when present in a nonreducing terminal position. The procedure is best explained by referring to an actual example. A pentaglycosylceramide of the globo series has the structure shown in Figure 4.[43] The glycosidic bond involving the nonreducing terminal α-*N*-acetyl-D-galactosaminosyl residue is specifically removed by the action of the purified α-*N*-acetyl-D-galactosaminidase from hog liver. In common with most glycolipid methods, a general protocol, applicable to all possible situations, cannot be given but some recommendations can still be made. First, the purity of the enzyme is paramount. Even traces of other glycosidase activities will yield erroneous results. The amphipathic nature of

Figure 4 Structure of the pentaglycosylceramide of the globo series showing how the sequential action of an α-*N*-acetyl-D-galactosaminidase, a β-*N*-acetyl-D-galactosaminidase, an α-D-galactosidase, a β-D-galactosidase and a β-D-glucosidase are required to determine the oligosaccharide sequence and anomeric configurations.

glycolipids means that a detergent such as sodium taurocholate is usually incorporated in the reaction buffer. The method is not just applicable to any nonreducing terminal residues. Addition of chloroform–methanol to the aqueous solution of reaction products gives a two-phase system with the released sugar residue in the upper aqueous phase and the remainder of the glycolipid, now containing one fewer sugar residue, in the lower phase. The released sugar residue is recovered and determined (see section 3.1.1) and the new glycolipid can be recovered and treated with another *exo*-glycosidase.

The method does have to be treated with some caution. If the internal α-D-galactosyl residue had been another α-*N*-acetyl-D-galactosaminosyl residue, its glycosidic bond would not have been susceptible to the *exo*-glycosidase. However, if the internal β-*N*-acetyl-D-galactosaminosyl residue had been another α-*N*-acetyl-D-galactosaminosyl residue, both α-*N*-acetyl-D-galactosaminosyl residues would have been hydrolyzed at the same time. The method is straightforward but, for an unknown glycolipid, can be time-consuming. The method, therefore, allows the carbohydrate sequence to be determined as well as the anomeric configuration of the different sugar residues. It cannot give any reliable information on the position of linkage to the next sugar residue in the sequence. Highly purified *exo*-glycosidases are now commercially available for each of the anomeric configurations of most of the sugar residues found in neutral glycolipids.

The gangliosides pose a greater problem. Sialidases have been isolated and purified but their activity is reported to be dependent on the environment of each sialic acid as well as the reaction medium. The presence of *N*-glycolyl and disubstituted neuraminic acids, as well as the more common *N*-acetyl residues, affects the specificity.

4.2 Linkage Analysis via Immunological Methods

The use of immunological methods has greatly expanded and the technique owes much to the work of Hakomori and Young.[44] One of the earliest reports[45] used monoclonal antibodies that had been raised against the terminal oligosaccharide sequences β-D-Galp-(1→4)-β-D-GlcNAc-(1→R) and α-L-Fucp (1→2)-β-D-Galp-(1→4)-β-D-GlcNAc-(1→R). Glycolipids carrying these sequences could be differentiated from each other. Because of their specificity, monoclonal antibodies are able to detect the individual sugar residue and its anomeric configuration as well as the linkage arrangement within a relatively short segment of the nonreducing terminus of the oligosaccharide component. As more specific monoclonal antibodies are produced, the range of sequences that can be characterized will increase. Furthermore, the combination of detection through the use of antibodies coupled with TLC and TLC blotting onto PVDF membranes leads to a level of detection that would not have been considered feasible even in the late 1980s.

As the general methods proposed are very similar to the original ones, two more recent examples are cited to show what is possible. Using monoclonal antibodies to type1 precursor, H-type 1, Le-a and Le-b epitopes, small quantities of Le-b blood group glycolipids were detected in a Lewis negative individual.[46] Previous studies by Marcus's group had produced seven murine monoclonal antibodies that were active against Le-x. Using a phage display library, two novel antibodies have been produced whose affinities are 10^2 higher than the originals.[47] As well as binding to Le-x, one of the new antibodies will bind to sialyl Le-x while the other will also bind to neolactosylceramide.

5 PHYSICAL METHODS OF ANALYSIS

5.1 Mass Spectroscopy

Of all the analytical methods and techniques that have been applied to the analysis of glycolipids, those involving MS have made the greatest impact since the late 1980s. Indeed, it is now very rare to see a research paper on glycolipids without some MS-related analysis or characterization. The theory of the different MS techniques, electrospray ionization (ESI), MALDI, FAB and so on, will not be addressed: there are many reviews currently available. This section will try to summarize the relevant techniques that can be applied to the analysis of glycolipids, giving as many examples from as wide a range of glycolipid types as possible.

One of the major advantages of MS is the very small sample size that can be analyzed. Another major asset is the ability to couple MS to other analytical instruments. GC/MS has been available for many years. The interface between MS and SFC is straightforward and LC/MS (liquid chromatography MS) is now in routine use. The earlier unreliability of the coupling interface between the two systems has largely been solved. Even the analysis of spots or bands on HPTLC is now compatible with MS largely through the use of blotting onto PVDF membranes (see section 2.4.1). Special mention will be made of combined methods such as collision induced dissociation FAB/(CID)/MS/MS (see later).

5.1.1 Matrix-assisted Laser Desorption/Ionization Methods

The technique of MALDI, as applied to oligosaccharides and glycoconjugates, has been reviewed[48] while specific results for glycosphingolipids[49] have been published.

Glycolipids, as well as the oligosaccharides derived from them, give mainly $[M + Na]^+$ ions which is in contrast to glycoproteins where $[M + H]^+$ ions are more abundant. Resolution is generally superior with ion cyclotron resonance and magnetic sector instruments over time-of-flight (TOF) instruments. Neutral glycolipids are able to produce strong spectra from a number of different matrices but the gangliosides do undergo extensive fragmentation due to the destruction of the sialic acid residues.

The best matrices for neutral glycosphingolipids are 2,5-dihydroxybenzoic acid (2,5-DHB), α-cyano-4-hydroxycinnamic acid and esculetin, particularly in the positive-ion mode. When *N*-acetylhexosaminyl residues were not present in the glycolipid and 2,5-DHB was used as matrix, fragmentation occurred between the carbohydrate and lipid revealing the structure of these components. With other matrices, loss of the acylamide from the ceramide was dominant and gave the distribution of C atoms between the acyl and sphingosyl groups. In contrast, when *N*-acetylhexosaminyl residues were present, fragmentation was not as specific but did allow much structural information to be gathered. For the gangliosides, loss of CO_2 and sialic acids both occurred while other fragment ions, derived from glycosidic cleavage, identified the carbohydrate sequence. The low-resolution MALDI spectra of the ganglioside G_{M2}, obtained with the matrices 2,5-DHB and esculetin are shown in Figure 5.

Other reports from Harvey's group have compared the structural information that can be obtained about the oligosaccharides using different methods of fragmentation, ways of stabilizing the sialic acid residues in gangliosides when using positive-ion MALDI methods and how the structure of the oligosaccharide will affect the signal strength in both TOF and magnetic sector instruments. A new technique, called delayed extraction MALDI, has been applied to the analysis of cerebrosides and sulfatides.[50] Both types of glycolipid were deacylated by microwave-mediated saponification and the long chain base components as well as the lysoglycosphingolipids could be characterized. Unlike classical methods, which only deacylate cerebrosides, the sulfatides are also deacylated and fewer by-products occur than are detected after acidic methanolysis.

A novel application for the sequencing of neutral oligosaccharides has been the combination of MALDI/MS with *exo*-glycosidase digestion.[51] The molecular mass profile is obtained by MALDI/TOF/MS using 2,5-DHB and 1-hydroxyquinoline as the matrix. The sample is then recovered from the target and the matrix removed by droplet dialysis. *Exo*-glycosidase digestion follows with the buffer and enzyme being removed by droplet dialysis and absorption onto a Nafion membrane, respectively, before a further MALDI/TOF/MS analysis. The cycle can be repeated as necessary. The method is designed to give more reliability to the sequence analysis as well as being much faster.

5.1.2 Fast Atom Bombardment Methods

The analysis of glycolipids has been simplified by the use of soft ionization techniques such as FAB. The structural characterization of the sulfoquinovosyl diacylglycerols from a cyanobacterium, dissolved in chloroform–methanol, in both positive ion (containing *m*-nitrobenzyl alcohol) and negative ion (containing triethanolamine) modes is shown in Figure 6.[52] The former gives $[M - H + 2Na]^+$ ions and the two main peaks at m/z 865 and 839 correspond to a total fatty acid composition of 34 : 1 and 32 : 0, respectively. The fatty acid profile is confirmed by the negative ions, $[M - H]^-$, at 819 and 793.

Another specific technique is the direct negative ion FAB/MS of glycosphingolipids separated on TLC plates.[53] The plates are moved within the ion source by a motor-driven probe. The technique has been optimized on neutral glycolipids containing five- and seven-sugar residues but has also been able to give a sequence determination for a highly branched eight-sugar glycolipid. As well as information on the oligosaccharide, molecular species with different ceramide compositions could also be detected.

5.1.3 Electrospray Ionization Mass Spectrometry

Electrospray ionization mass spectrometry (ESIMS) is another type of soft ionization that has been shown to give molecularly related ions with high sensitivity and accuracy. It is reported to be very accommodating for polysialogangliosides and the spectrum of a tetrasialoganglioside has been published.[54] There are references to the technique alone but it is likely to be more useful in conjunction with other secondary techniques such as MS/MS/CID/MS/MS.

5.1.4 Liquid Secondary Ion Mass Spectrometry

This technique has been used for sulfated gangliosides.[55] From the normal negative liquid secondary ion mass spectrometry (LSIMS) spectra, monosulfated species gave $[M - H]^-$ ions while bis-sulfated species gave $[M + Na - H]^-$ ions. In the high-energy CID spectra, only ions containing sulfate esters were detected, with major differences depending whether the sulfate group was attached to a nonreducing terminal residue or was present on an inner hexose residue. The low-energy CID spectra were very simple with only one or two product ions, specific for each sulfated glycolipid, being detected. Combining the data, oligosaccharide structures differing in location and number of sulfate esters could be distinguished from each other.

Figure 5 MALDI mass spectra of the ganglioside G_{M2} with 2,5-DHB (a) and esculetin (b) as the matrices.[49] (Reprinted with permission of John Wiley & Sons, Chichester from *J. Mass Spectrom.*, **30**, 1311–1324 (1995).)

5.1.5 Tandem Mass Spectrometry

MS/MS, as its name implies, employs two stages of mass analysis. The general aim is to produce particular, often molecular, ions in one system and then to fragment these ions in another system. The fragment ions produced in the second system will be characteristic of the compound. In theory, two isomeric compounds could produce molecular ions of similar mass but should be differentiated by the fragmentation pattern. The technique, as applied to glycolipids, has been reviewed[56] and some examples are given below.

The sulfoquinovosyldiacylglycerols, discussed under FAB (see section 5.1.2),[52] had a major molecular ion $[M - H + 2Na]^+$ at m/z 865 in the positive-ion FAB spectrum. The high mass region, obtained from the CID breakdown of this ion (see Figure 7: an MS/MS system), had ions at m/z 739, 725, 711, 697, 683, 669 and 655 ($^3I_1$) which are characteristic of an 18:1 unsaturated fatty acid group, namely oleic acid, at C-1. The ions at

5. α-D-GalpNAc-(1→3)-β-D-GalpNAc-(1→3)-α-D-Galp-(1→4)-β-D-Galp-(1→4)-β-D-Glcp-(1→1)-ceramide

m/z 737, 723, 709, 695 and 681 ($^3I_2$) are due to a 16:0 saturated fatty acid, palmitic acid, at C-2. In contrast, the predominant molecular ion $[M + Na]^+$ at *m/z* 801 from monogalactosyldiacylglycerol contained linoleic (18:2) acid residues at both C-1 and C-2.

The gangliosides discussed in the ESIMS section (see section 5.1.3)[54] were further characterized by CID MS/MS. Using both negative and positive ion modes, the isomeric disialogangliosides, G_{D1a} and G_{D1b}, were readily distinguishable showing that the method should be applicable to any positional isomers of glycolipids. A final example is the characterization of glycosphingolipids from bovine erythrocytes.[57] By comparison with authentic samples, detection levels in the ranges 10^{-15}–10^{-9} mole are quoted for mono- and difucosylated glycolipids of the neolactose series. These glycolipids are very minor components found in the central nervous system but are reported to be of major biological importance.

5.2 Nuclear Magnetic Resonance Spectroscopy

5.2.1 ^{1}H Nuclear Magnetic Resonance

NMR spectroscopy has been applied to the analysis of intact glycolipids, their peracetyl and permethyl derivatives as well as oligosaccharides released from them (see section 3.2.1) but, compared with mass spectrometry, it is less usable owing to the relatively large amount of material needed for analysis. The choice of procedure is dependent on the information required. However, when any possible interrelationship between the different components of the glycolipid are required, the intact and underivatized glycolipid must be used. The ^{1}H signals from the ceramide component can all be unambiguously assigned and do not overlap with any of the carbohydrate signals. For the oligosaccharide component, the ^{1}H signals from the glycosidic protons are well separated from all the other ring protons.

Dabrowski, Hanfland and Egge[58] reviewed the earlier applications. Although the data is quite old, the chemical shifts and coupling constants given in Table 1 are reliable enough to confirm the structure of the carbohydrate component of a pentaglycosylceramide of the globo-series (see Figure 4) and its lower homologues.[59] Even with a low field instrument, the size of the coupling constant of each glycosidic proton gives its anomeric configuration. In the example cited in Table 1, the coupling constants for the α- and β-*N*-acetyl-D-galactosaminosyl and α- and β-D-galactosyl residues are distinct. Apart from sugars with the manno-configuration, α-glycosidic protons have $J_{1,2}$ coupling constants of 3–4 Hz while β-anomers show values of 7–9 Hz. As with other procedures, the amphipathic nature of glycolipids means that special solvent systems are necessary for dissolution. Many reports use 2% D_2O in deuterated DMSO while others use pyridine-d_5.

The introduction of instruments with field strengths up to 800 MHz can give unambiguous results with as little as 100 μg of glycolipid. Future generations of instruments are unlikely to improve significantly on this lower limit. For a straightforward 1-D ^{1}H spectrum, 400 MHz instruments allow the coupling constants to be obtained not only of the anomeric protons but all of the protons attached to the ring carbon atoms to be assigned and determined. Thus, an unambiguous assignment of each sugar residue and its configuration is obtained.

The theory and practice of NMR spectroscopy has advanced greatly since the mid 1970s with the introduction of 2-D spectroscopy and related methods and there are many general reviews (see, for example, Goldman).[60] Few are specifically applied to glycolipids although animal glycerosphingolipids have been reviewed[61] and plant glycodiacylglycerols[42] are included in a general review. The different types of 2-D NMR spectra can be classed under shift correlation spectroscopy (COSY) methods or spin-lattice relaxation methods. The latter are due to the time-dependent interaction between two spins

producing a cross-reaction, or nuclear Overhauser effect spectroscopy (NOESY). There are further refinements of each technique and for more information relevant papers should be consulted.

As one example, the conformational analysis of the ganglioside G_{D1a} has been determined by a NOESY method (see Figure 8 for 2-D spectra).[62] The inter-residual hydrogen distances calculated from the NMR data were in good agreement with the lowest energy model previously suggested. The internal and branched sialic acid residue is stacked underneath the *N*-acetyl-D-galactosamine residue with a hydrogen bond between the carboxy group of the sialic acid and the amino group of the *N*-acetyl-D-galactosamine residue. Both sialic acid residues are orientated almost perpendicular to the plane of the neutral tetrasaccharide core. By contrast, the structural analyses of the oligosaccharide chains of glycolipids were determined by magnetic transfer methods.[63] COSY and homonuclear Hartmann Hann (HOHAHA) methods were able to extract subspectra of constituent monosaccharides and identify their sugar type.

Figure 8 Slices from the 2-D NOESY spectrum of the ganglioside G_{D1a} at 200, 400 and 800 ms corresponding to the chemical shift of H-3^{f}_{ax} (a–c) and H-3^{e}_{ax} (d–f), respectively.[62] (Reprinted with permission of the American Chemical Society from *J. Am. Chem. Soc.*, **113**, 3236–3246 (1991).)

NMR has been used to understand the arrangement of glycolipids in bilayer membranes.[64] The sphingolipid metabolites behaved as single populations of lipid amphiphiles that were uniformly dispersed in the membrane and displayed rapid symmetric motion about their long molecular axis. The whole area of the application of NMR to lipid phase behavior and lipid diffusion has been reviewed.[65]

5.2.2 ^{13}C Nuclear Magnetic Resonance

Far more structural information can be obtained from a ^{13}C-NMR spectrum than from ^{1}H-NMR. Owing to the low natural abundance of the ^{13}C isotope, the technique does suffer from the need for relatively large quantities of the native glycolipid. A specific example of the technique was the elucidation of the structure of the digalactosyldiacylglycerol present in oat grain.[66] By using ^{13}C-NMR, as well as ^{1}H-NMR, the identity of the glycosyl moieties in the polar head group, the linkage position between the groups and the anomeric configuration of the moieties were all determined.

^{13}C-NMR has also been used to determine the positional distribution of fatty acids in glycoglycerolipids from different plant families.[67] The acyl carbonyl shifts of fatty acids attached at C-1 are downfield from those of C-2. In addition, the shifts also depend on the distance to the nearest double bond. Hence, plant families with high proportions of all-*cis*-Δ-7,10,13-hexadecatrienoic and all-*cis*-Δ-6,9,12,15-octadecatetraenoic acids could be determined and the results were in agreement with the distribution as determined using a lipase.

ACKNOWLEDGMENTS

The author wishes to thank the following for permission to publish data and figures from published material: Academic Press, New York, for permission to publish data for Figures 2 and 3, John Wiley & Sons, Chichester, for permission to publish data for Figures 5, 6 and 7 and American Chemical Society for permission to publish data for Figure 8.

Glycosylation is a common co- and post-translational modification of a protein which may have profound effects on protein structure and function. Many biologically interesting proteins are glycosylated at their asparagine, serine, and threonine residues. Glycosylation has now been recognized as being more ubiquitous and structurally varied than all other types of post-translational modifications combined. The glycosylation pattern of a glycoprotein is not random but is dependent on cell type, physiological conditions and, in some cases, disease states. Carbohydrate chains or glycans attached to the peptide backbone are classified according to the nature of the linkage to the peptide and their structure; both of these parameters allow the definition of common cores. In addition to the extreme structural diversity and complexity of glycan structures, one feature of protein glycosylation is the presence at a single site of any one of a number of glycan structures. This property gives rise to an extremely heterogeneous population of glycoproteins, termed glycoforms. The complexity of the glycan structures, the multiple substitutions (microheterogeneity) at glycosylation sites, and the structural diversity associated with the protein backbone itself represent an enormous task for analytical structural studies.

Indirect methods such as immunological approaches using antibodies or lectins provide some structural information concerning the nature of glycans. Prior to their structural study, glycans have to be released from the protein backbone by enzymatic or chemical methods. Different endoenzymes such as N-glycanase® allow a complete deglycosylation of glycoproteins, providing a pool of oligosaccharides which may be further fractionated. Establishment of the site heterogeneity and assessment of the different glycoforms require isolation and analysis of the individual glycopeptides generated after hydrolysis with specific proteases. Fractionation of glycans or glycopeptides can be achieved by different high-performance liquid chromatography (HPLC) or electrophoretic procedures. Lectins, due to their extreme specificities with regard to monosaccharide or oligosaccharide motifs, represent powerful tools for sequential glycan fractionation. Traditionally, a complete structural analysis of the glycan structures, including determination of the carbohydrate sequence and the sugar linkage, has been a tedious, multidisciplinary task. Characterization and determination of the relative amount of individual constituent monosaccharides is generally obtained by gas–liquid chromatography (GLC) after hydrolysis of the oligosaccharide chain. Information concerning the nature of linkages and branching points is furnished by the methylation procedure. Nevertheless, these chemical sequencing methods often necessitate milligrams of material. To progress from this situation, sensitive physicochemical or enzymatic methods have been developed. The nuclear magnetic resonance (NMR) study of oligosaccharides, even of the less sensitive of the physicochemical techniques, is extremely powerful because it allows determination in a mixture of glycans, the complete structure of individual glycans including nature of monosaccharides, sequence, type of linkages, anomericity and branching points. The recent advances in mass

spectrometry (MS) techniques, mainly matrix-assisted laser desorption/ionization (MALDI) or electrospray ionization (ESI), have provided very sensitive means for the analysis of oligosaccharides and glycopeptides. The gain in sensitivity associated with a minimum number of sample manipulation steps allows work at the submicrogram level. The use of enzyme reagents is rapidly becoming popular in modern carbohydrate analysis because of their inherent selectivities for a sugar substrate and its linkage type. Exoglycosidases can be used in conjunction with other methods such as MALDI/MS or fluorophore-assisted carbohydrate electrophoresis (FACE) separation. Complete structural information is now feasible for low-microgram and submicrogram quantities of a glycoprotein; this quality of performance places the field of carbohydrate analysis closer to the sequencing methods available for other biomolecules, proteins or nucleic acids.

1 INTRODUCTION

In 1907, The American Society of Biological Chemists and the American Physiology Society defined the glycoproteins as ''compounds of the protein molecule with a substance or substances containing carbohydrate other than nucleic acid''. In 1986, the International Union of Pure and Applied Chemistry–International Union of Biochemistry (IUPAC–IUB) Joint Commission on Biochemical Nomenclature[1] described glycoconjugates as various types of compound consisting of carbohydrates covalently linked with other types of chemical constituent. This general definition of glycoconjugates includes glycoproteins, glycopeptides, glycolipids, peptidoglycans, and lipopolysaccharides.

This article refers only to glycoproteins and glycopeptides, which are compounds containing one or more oligosaccharides or glycans covalently linked to the polypeptide chain by a glycosyl linkage.

According to the type of glycosylation, the family of glycoproteins may be subdivided into glycoproteins, mucins, and proteoglycans. The glycans linked to the polypeptide chain of the proteoglycans are called glycosaminoglycans. The glycosaminoglycans are linear polymers of alternating residues of hexosamine and uronic acid or galactose. They are often sulfated at various positions.[2,3] A survey of methodological challenges for glycosamino glycan/proteoglycan analysis has been published recently.[4] The glycoproteins are ubiquitous components. They result from an enzymatic addition of glycans to the proteins biosynthesized by viruses, many archaebacteria, some eubacteria, plants, and animals. The glycosylation step of a protein represents one of the most important post-translational modifications of this protein.

Glycoproteins are widely distributed in biological fluids mainly in serum, intracellularly, and at cell surfaces. The mucins are highly glycosylated proteins found at the surface of all mucosa. Mucin-like components have been identified at cell surfaces, mainly in cancer cells. Significant advances in the understanding of the structure and the biosynthesis of glycoproteins have revealed that different glycans may be linked to an individual glycosylation site, leading to a mixture of glycovariants or glycoforms within a single polypeptide chain.[5] In parallel with our increasing knowledge of the glycoprotein structures, important functional roles of glycans have been recognized, not only in the modulation of the conformation and the physicochemical properties of the protein, but also in the biological interactions of the glycoforms with free or membrane target molecules. Most of the recent advances in structure and function of the glycoproteins have been extensively reviewed.[6–11]

Recombinant antibodies, hormones, and enzymes are now produced for clinical applications. A connection between the biological functions of these recombinant glycoproteins and the structure of their glycans has been established.[12] Arising from the importance of the development of genetic engineering techniques for the production of recombinant glycoproteins, techniques are becoming necessary for rapid and reliable determination of the glycan structure as well as for the glycan distribution among the different glycosylation sites.

This article describes the general features of the glycan structures found in glycoproteins and mucins, and a combination of chromatographic techniques is proposed for their isolation and structural characterization.

2 GLYCAN STRUCTURES: AN OVERVIEW

Recent advances in the physical methods used to determine the primary structure of glycoprotein glycans now enable the analysis of very small amounts of material. This has rapidly increased the number of glycan structures, more than 1500 of which are now gathered in the CarbBank. The diversity of these glycans is mainly explained by the nature of the covalent carbohydrate–protein linkage, the composition in monosaccharides, the branching of the structures, and the origin of the glycoproteins.

2.1 Carbohydrate–Protein Linkage

For a long time the only two types of covalent linkages known were *N*-glycosylated (alkali stable) and *O*-glycosylated (alkali labile). In the N-linked glycans, the nitrogen of the side chain of an asparagine is linked to the β-anomeric carbon of an *N*-acetylglucosamine

Table 1 Linkage between glycan and polypeptide chain

Type	Mono-saccharide	Amino acid	Occurrence
N-Glycoside	β-GlcNAc	Asn	Common
	β-GalNAc	Asn	Archaebacteria
	β-Glc	Asn	Archaebacteria
	α/β-Glc	Asn	Animals
	L-Rha	Asn	Eubacteria
O-Glycoside	α-GalNAc	Ser/Thr	Animals (mucin type)
	β-GalNAc	Ser/Thr	Animals
	β-GlcNAc	Ser/Thr	Animals (intracellular type)
	α-Xyl	Ser	Animals (collagen type)
	α-Fuc	Ser/Thr	Animals
	β-Gal	Hyp	Animals
	α-Glc	Tyr	Animals (glycogenin type)
	β-Glc	Ser/Thr	Animals, eubacteria
	α-Man	Ser/Thr	Animals, yeasts
	α-Gal	Hyp/Ser	Plants, eubacteria
	β-L-f-Ara	Hyp	Plants
	β-Gal	Tyr	Eubacteria
C-Glycoside	α-Man	Trp	Human RNase

GlcNAc, *N*-acetyl-D-glucosamine; GalNAc, *N*-acetyl-D-galactosamine; Glc, D-glucose; Xyl, D-xylose; Fuc, L-fucose; Gal, D-galactose; Man, D-mannose; f-Ara, L-furanoarabinose; Hyp, hydroxyproline; Tyr, tyrosine; Trp, tryptophan.

and constitutes the 2-acetamido-*N*-(L-aspart-4-yl)-2-deoxy-β-D-glucopyranosylamine or N^4-(*N*-acetyl-β-D-glucosaminyl)asparagine linkage. The asparagine residue belongs to the peculiar sequon AsnX (Ser or Thr, and rarely Cys) of a polypeptide chain (Asn = L-asparagine; Ser = serine; Thr = threonine; Cys = cysteine). Here X is any amino acid except proline (which completely blocks the glycosylation) and some amino acids such as tryptophan, glutamic acid, aspartic acid, or leucine (which create conformational constraints and partially inhibit the glycosylation). All Asn residues included in the triplet are not glycosylated, because the glycosylation depends on the accessibility of the sequon to the oligosaccharyltransferase, which transfers the complete immature oligosaccharide to the asparagine. In bacterial glycoproteins, the *N*-acetylglucosamine linked to Asn is replaced by an *N*-acetylgalactosamine, a glucose, or a rhamnose residue (Table 1).[13] In *O*-glycosidically linked glycans, the anomeric carbon of a monosaccharide is attached through an α- or β-*O*-glycosidic linkage to the hydroxyl oxygen of serine, threonine, hydroxylysine, hydroxyproline or tyrosine (Table 1).[13] The *N*-acetyl-α-D-galactosaminyl-Ser or -Thr is the most common carbohydrate–protein linkage found in the mucins. Proposed peptide motifs containing Ser and Thr specifying *O*-glycosylation sites have been described[14] and a database containing the sequences around *O*-glycosylation sites is on the Internet. Recently, a fundamentally different kind of protein glycosylation has been found in which the C2 atom of tryptophan is attached by a C–C linkage to the anomeric carbon of an α-mannose residue.[15] This *C*-mannosylation of tryptophan has been shown by tandem electrospray MS analysis in human ribonuclease 2. In addition to *N*-, *O*-, and *C*-glycosyl linkages, in membrane glycoproteins, the anchor of the glycolipid glycosylphosphatidylinositol (GPI) is conjugated to the protein *C*-terminus through an amide bond.[16]

2.2 Carbohydrate Composition

A landmark for the carbohydrate composition of a mature *N*-glycosylated protein is the presence of the monosaccharides D-mannose (Man), *N*-acetyl-D-glucosamine (GlcNAc), D-galactose (Gal), L-fucose (Fuc), *N*-acetyl-D-galactosamine (GalNAc), D-xylose (Xyl), L-furanoarabinose (f-Ara), and sialic acids which are various derivatives of neuraminic acid,[17] mainly *N*-acetyl-neuraminic acid (Neu5Ac) and *N*-glycolylneuraminic acid (Neu5Gc). During biosynthesis,[18] immature glycans contain one to three residues of Glc involved in the trisaccharide structure Glc(α1–2)Glc(α1–3)Glc(α1–3) linked to the oligomannosidic type glycan $Man_9GlcNAc_2$. The presence of glucuronic acid (GlcA) is not common in N-linked glycans. In O-linked glycans, the main monosaccharides are GalNAc, Gal, GlcNAc, Fuc, and sialic acids. Even if mannose has been found in some O-linked glycans, it is considered to be unusual here. Other peculiar monosaccharides,[13] such as the deaminated neuraminic acid 2-keto-3-deoxynononic acid (Kdn) and various *O*-sulfated, *O*-phosphorylated, *O*-methylated and methyl *O*-phosphorylated monosaccharides, have been identified either in O- or N-linked glycans. The monosaccharides found in glycoproteins have the pyranose configuration and sometimes the unusual furanose configuration.

2.3 N-linked Glycoproteins

2.3.1 General Structure of N-*Glycans*

The structure of N-linked glycans is very heterogeneous; however, all glycans possess a pentasaccharide core constituted of two *N*-acetylglucosamine and three mannose residues (Figure 1). This backbone may be substituted either by one *N*-acetylglucosamine (known as the intersecting GlcNAc residue), one xylose, or one to two fucose residues. The complexity of the glycan structures results from the addition to Man(α1–3) and Man(α1–6) of one to five *N*-acetylglucosamine residues. In fact, these

Figure 1 Modifications of the pentasaccharide core of *N*-glycosylated proteins.

Figure 2 Side chains in *N*-acetyllactosaminic or complex-type glycans.

GlcNAc initiate a branching and generate di-, tri-, tri′-, tetra-, and pentaantennary glycans[19] (Figure 1). In mature glycans, extension of the branching is realized by addition of various peripheral structures including Gal, GlcNAc, GalNAc, Fuc, and sialic acids in order to complement the antennae (Figure 2). The glycan structures obtained are called *N*-acetyllactosamine or complex type, and when the extension consists of several *N*-acetyllactosamine units (Gal(β1−4)GlcNAc) associated by a (β1−3) linkage, the structures are called polylactosamine type.

Analysis of the three-dimensional structure of glycans has revealed that the pentasaccharide core is rigid whereas the antennae are mobile. The glycans have interactions with the polypeptide chain and occupy an important volume at the surface of the glycoprotein.[20,21]

2.3.2 Biosynthesis of N-*Glycans*

Biosynthesis of the N-linked glycans and the control of glycosylation induced by the conformation of the polypeptide chain are now well established. This biosynthesis involves, in the first step, the transfer of the oligosaccharide ($Glc_3Man_9GlcNAc_2$) from a dolichyloligosaccharide precursor to the nascent polypeptide chain. Mature glycans are obtained following the activity of trimming glycosidases (α-glucosidases and α-mannosidases) and specific glycosyltransferases found in the endoplasmic reticulum and the Golgi apparatus.[22,23] During the biosynthesis, it may be noticed that the glycan structure is affected by the compartments traversed within a cell and also by the speed with which the glycoprotein passes through these different compartments. Examples of oligomannose or high mannose, hybrid and biantennary *N*-acetyllactosamine glycan structures obtained during the biosynthesis pathway and found in the structure of native glycoproteins are given in Figure 3.

2.3.3 Variability of Glycosylation

A systematic and comparative study on glycan primary structures of transferrin from biological fluids of different species has revealed that the glycosylation pattern of the individual transferrin molecule depends

Figure 3 Representative structures of the three types of *N*-glycosidically linked glycans.

on the glycosyltransferase activities of the cell and of the species.[24] The cell specificity, tissue specificity and species specificity of glycosylation are now well established and have important implications.[5,21] For instance, the glycosylation pattern of recombinant glycoproteins is highly dependent on the glycosyltransferase activities of the cell. As only few bacteria possess glycosylation capacity, yeast, insect cells, plants, and animal cell lines have often been used as systems for expressing recombinant glycoproteins.[25] Examples of typical glycan structures biosynthesized by various cells are given in Figure 4.[26–30] The high variability of the glycan structures found in a given recombinant glycoprotein expressed in various cells may provide an explanation for some divergences in the physicochemical, biochemical, immunological and functional properties of the resultant recombinant glycoforms.

A specific set of glycans is attached to a unique glycosylation site. For instance, in human serum transferrin, the two glycosylation sites are occupied by either bi-, tri-, tri′, or tetraantennary glycans leading to different glycoforms.[24] These glycoforms have been separated using lectin-affinity chromatography, anion-exchange chromatography, isoelectric focusing or ESI/MS. In normal physiological conditions, the percentages of these glycoforms are reproducible. However, high variations in these percentages appear during development, differentiation, and under modifications of the normal physiological state. The nature of the different factors involved in the alterations of glycosylation is not yet known; however, the modulatory effects of hormones or cytokines during pregnancy[31] or inflammation[32] have been described.

2.3.4 Biological Roles of N-linked Glycans

The *N*-glycans are recognized as components having many functional roles[33–36] and the new science of glycobiology has been developed. It is difficult to predict the function of a given glycan, because the same glycan may be associated with various functions in different glycoproteins. Of the numerous functions attributed to *N*-glycans, some are important to the glycoprotein itself, mainly for its folding, solubility, protease sensitivity, antigenicity, intracellular location, and biological half-life. In general, the peripheral sequence of a glycan represents the most important functional part of this glycan. This peripheral part may be involved in specific carbohydrate–carbohydrate interactions or carbohydrate–protein interactions which generate most of the biological processes in which the glycoproteins are involved. For instance, the mechanism of recognition is responsible for the following: binding of asialoglycoproteins to the hepatic cell receptor which specifically recognizes terminal Gal and GalNAc residues and which is involved in the clearance of the asialoglycoproteins;[37] the specific binding of pathogens to the cells of the immune system;[38] or the specific targeting of enzymes possessing a glycan with Man-6P to the lysosomes.[39] An aberrant glycosylation of glycoproteins may alter

Figure 4 Examples of *N*-glycosidically linked glycans.

the intra- and intermolecular functions of the glycans. The science of glycopathology is now developing and some correlations between the modifications of glycosylation patterns and pathology have been established.[40] A better understanding of the fine variations in glycan structures and in the relative proportions of the glycoforms, at different stages of a disease, appear relevant to diagnosis.

Progress in genetic engineering has allowed the biosynthesis of a multitude of recombinant glycoproteins used for pharmaceutical applications. The most important problem encountered concerns the biosynthesis of a panel of glycoforms, which should be similar to the panel biosynthesized in vivo. Variations in glycosylation of recombinant glycoproteins may induce alteration in intercellular targeting and clearance[41] and may therefore inhibit their therapeutical activity.

2.4 O-linked Glycoproteins

2.4.1 General Structure of O-linked Glycans

In glycoproteins such as yeast glycoproteins,[30] secretory immunoglobulin A,[42] and glycophorin,[43] a limited number of O-linked glycans is found associated with N-linked glycans, whereas in mucins, several hundred to several thousand of these glycans are clustered in highly glycosylated domains.[44] The structure of the *O*-glycans is also very heterogeneous. The diversity depends on the nature of the core and the chain length, which may comprise 1–20. All these glycans are based on the same structural model, made of three distinct regions: the core, the backbone, and the periphery. To date, eight cores including the GalNAc attached to the hydroxy amino acid and Gal, GlcNAc and GalNAc residues have been characterized (Figure 5).

Cores

1 Gal(β1–3)GalNAcα

Figure 6 Examples of *O*-glycosidically linked glycans.

Linked to the cores are six types of backbone, the most common being the *iso*-*N*-acetyllactosamine unit (Gal(β1–3)GlcNAc; type I) and the *N*-acetyllactosamine unit (Gal(β1–4)GlcNAc; type II). The periphery is made of different monosaccharides (Gal, GalNAc, Fuc, NeuAc) which may be assembled in repeated units. Examples of typical and peculiar O-linked glycans found in various glycoproteins are given in Figure 6.[45–48]

2.4.2 Biosynthesis of O-linked Glycans

In contrast to the biosynthesis of N-linked glycans, the biosynthesis of *O*-glycans is not performed by a transfer from a dolichyl–oligosaccharide precursor to the protein, but by a sequential addition of a monosaccharide from a nucleotide monosaccharide. In mucins, the UDP-GalNAc polypeptide α-*N*-acetylgalactosaminyltransferase is the enzyme which conjugates the first GalNAc residue to the completely folded apoprotein. Several types of this enzyme have been characterized. The eight cores result from the addition of Gal, GlcNAc, and GalNAc residues by α- or β-glycosyltransferases, whereas the backbones are synthesized by the action of two types of β-galactosyltransferase and two types of β-*N*-acetyl-glucosaminyltransferase. Addition of the monosaccharides found in the peripheral part is performed essentially by α-glycosyltransferases. The numerous glycosyltransferases involved in the biosynthesis of *O*-glycans are specific and almost localized in the Golgi apparatus.[49,50]

2.4.3 Biological Roles of O-linked Glycans

Like the N-linked glycans, the O-linked glycans are involved in intra- and intermolecular interactions and these interactions are increased by the fact that the *O*-glycans are often found in glycoproteins and mucins as clusters.[44,51] The presence of a cluster of sialylated and sometimes sulfated *O*-glycans confers to the polypeptide chain an extended conformation, a protection against the protease activity and heat denaturation. *O*-Glycans present in membrane glycoproteins have been recognized as receptors for viruses, bacteria, and pathogens. Antigenic determinants responsible for A, B, H, Le^x, Le^y, and

Figure 7 Structure of blood group determinants.

sialyl Le^x blood group activities are largely distributed among the glycoproteins containing O-linked glycans[52] and are located at the periphery of the structures (Figure 7). *O*-Glycosylation plays an important role in the mechanism of cell–cell recognition. For instance, in the mechanism of leukocyte adhesion to activated endothelial cells, specific structures of *O*-glycans are recognized by animal lectins called selectins.[53] During fertilization, the spermatozoon binds to *O*-glycans located in the mucins of the zona pellucida of the ovocyte. The specificity of these *O*-glycan structures should offer an explanation for species specificity in fertilization.[54] Alterations of *O*-glycosylation result in various pathologies, in cancer development, and in metastasis,[55] and the *O*-glycan structures are generally decreased.

2.5 Structure and Biosynthesis of Glycosylphosphatidylinositol Anchors

These anchors are complex structures sharing a common structure in which the inositol from a membrane glycerophosphatidylinositol is linked to a glucosamine residue from the linear tetrasaccharide Man(α1–2) Man(α1–6)Man(α1–4)GlcNH_2(α1–6). The diversity of GPI anchor structure depends on substitution of the core. Although little is known about the enzymes involved in the biosynthesis of a GPI anchor, the different steps in the biosynthesis of the trypanosomal GPI anchors have been well established.[56] The methods used to isolate and identify the complete structure of a GPI anchor are not described here.

3 GLYCOPROTEIN ISOLATION AND CHARACTERIZATION

Many methods are available for glycoprotein isolation. The conventional chromatographic methods of glycoprotein fractionation are based on molecular mass (gel permeation chromatography), surface charge interactions (ion-exchange chromatography) and surface hydrophobic interactions (hydrophobic chromatography). More selective glycoprotein isolation methods are based on interactions of the protein moiety with specific monoclonal or polyclonal antibodies (immunoaffinity chromatography) and the interactions of glycan moiety with lectins (lectin-affinity chromatography).

The use of these different column chromatography techniques (alone or in combination, performed at low or high pressure) can isolate pure glycoproteins (in a single step or in several steps). The purified glycoproteins are often composed of a mixture of glycoforms which differ by their degree of sialylation and therefore by their isoelectric point. To isolate the glycoforms, additional methods are often necessary based on electrophoresis, such as capillary electrophoresis, sodium dodecyl sulfate/polyacrylamide gel electrophoresis (SDS/PAGE), and isoelectric focusing.

This review concentrates first on immunoaffinity chromatography, which can be used (if specific antibodies are available) before other methods to extract a pure glycoprotein from a sample. Secondly, anion-exchange chromatography and lectin-affinity chromatographic methods, which are able to separate the glycoforms, are considered.

3.1 Mucin Isolation

3.1.1 Isolation of Mucins Requires Specific Methods

Due to their high molecular weight and their extreme diversity both in peptidic backbone and carbohydrate content, the isolation of mucins requires specific isolation methods.[57–59] Mucin can be collected from mucosal cells by scraping of the tissue surface using guanidine hydrochloride/phosphate-buffered saline

(PBS) at pH 7.0. Generally mucins are contaminated with proteoglycans, nucleic acids, and other glycoproteins. The first steps of purification consist of molecular-weight-based fractionation using repeated ultracentrifugation on a cesium chloride gradient in the presence of concentrated guanidine solutions. The samples are centrifuged at 100–150 000 *g* for 24–48 h in order to generate a density gradient from 1.3 to 1.6 g mL^{-1}. Under these conditions, proteoglycans, nucleic acids, and mucins are well separated.

Further purifications steps of individual mucins can be achieved according to molecular size using gel filtration on Sepharose™ CL2B or Sephacryl S1000. As a result of their charge diversity in relation to their sialic acid and/or sulfate content, individual mucin glycoforms can be separated by anion exchange chromatography on an anion exchanger such as diethylaminoethyl (DEAE). All of these chromatographic procedures should be carried out in the presence of strong denaturating agents such as guanidine hydrochloride buffer, or by introduction of reducing agents such as dithiothreitol (1% w/v).

If subunits are required, reduction and alkylation of mucin samples are necessary. Finally, strategies based on immunoaffinity procedures, using specific antibodies directed against the tandem repeat of the protein backbone such as the Pro-Asp-Thr-Arg-Ala-Pro-Gly-Ser (PDTRAPGS) region, have been recently developed and may be used in the isolation of abnormal mucins expressed in pathological states such as cancer.

3.2 Immunoaffinity Chromatography

A one-step purification of glycoprotein may be performed using specific protein monoclonal or polyclonal antibodies immobilized on different supports. Numerous methods have been used for preparing immobilized antibodies. Protein immobilization to CNBr-activated gel (agarose, Sepharose™, Ultrogel®) is the most popular choice.[60,61] A major drawback found in protein affinity gel preparation by activation of Sepharose™ with CNBr concerns the introduction of charged groups into the matrix. This is avoided when the proteins are immobilized on polyacrylic-hydrazido-Sepharose™ support.[62] Immobilized proteins can also be prepared with activated agarose-containing *N*-succinimide esters that react with amino groups of the proteins.[63]

In addition to these general techniques used for all kinds of proteins and many lectins, oriented immobilization methods have been described for antibodies. The different techniques of oriented immobilization of antibodies have been reviewed, such as the use of immobilized protein A or G, the use of immobilized antibodies against the Fc constant region of the antibodies to be immobilized, and the use of immobilized antibodies through the carbohydrate moiety after acid periodic oxidation.[64]

The selection methods for the most appropriate monoclonal antibody to be immobilized and precise methods for binding, washing and the elution steps have been reviewed.[65] In general, once the glycoprotein has been captured by the specific immobilized antibodies, elution of the glycoprotein is performed in acidic conditions and, to preserve the biological activity of the purified antibodies, eluted antibodies must be immediately neutralized.

Immunoaffinity chromatography is also used for detection of analytes as they elute from other types of chromatographic columns. Advances in analytical applications of immunoaffinity chromatography have been recently reviewed.[66]

3.3 Isolation of Glycoforms by Anion-exchange Chromatography

The glycoforms often differ by their charge and can be separated preparatively by using anion-exchange chromatography after careful optimization of the analytical conditions. For instance, to separate the 14 glycoforms of recombinant human erythropoietin, different methods of fractionation were used with the best results being obtained by DEAE-Sephacel chromatography.[67] Anion-exchange HPLC has been used to fractionate mucins and to identify glycoforms.[68] A very rapid separation of monosialylated and disialylated serum transferrin glycoforms was obtained by ion-exchange chromatography on a Mono Q HR 10/10 column using fast protein liquid chromatography (FPLC).[69]

3.4 Isolation of Glycoforms by Lectin Affinity Chromatography

3.4.1 Problems of Lectin Specificity

Lectins are sugar-binding proteins or glycoproteins of nonimmune origin that can agglutinate cells and/or precipitate glycoconjugates.[70]

They possess at least two sugar-binding sites, the presence of which explains their ability to precipitate polysaccharides, glycoproteins, or glycolipids, and why they agglutinate cells.

Lectins have been now isolated from viruses, bacteria, plants, and from a variety of animal tissues and species. However, only plant lectins are now commonly used in research and in clinical laboratories for the detection and fractionation of soluble and membrane glycoproteins, as well as glycopeptides or glycans derived from these glycoproteins.[71–73]

Lectins are often still classified according to the monosaccharide that inhibits the interaction between a lectin and a cell, or which allows the specific elution of a

Table 2 Lectins commonly used for glycoprotein study, classified according to their monosaccharide specificity

Lectin	Abbreviation
α-Man, α-Glc

bound glycoconjugate from an immobilized lectin column (Table 2).

Analysis of sequence data of plant lectins by protein sequencing and cDNA cloning, together with X-ray crystallography data and molecular modeling, result in classification by their three-dimensional structures, not taking into account their monosaccharide-binding specificities.[74–76] In this way seven groups of plant lectins can be distinguished:

- The legume lectins with a 12-stranded β-sandwich structure.
- The monocot-binding lectins with a 12-stranded β-barrel structure.
- The Jacalin-like lectins with a β-prism fold.
- The Amaranth-like lectins.
- The chitin-binding lectins made of hevein-like domains.
- The type II ribosome-inactivating proteins (RIPs) which contain an enzymatically active A chain and a B chain with lectin activity.
- The cucurbitaceae phloem lectins, which are a small family of chitin-binding lectins, found in the phloem exudate of cucurbitaceae species.

The structural basis of selective monosaccharide recognition by plant lectins has been investigated by X-ray crystallography and is now well documented.[77,78] It explains in terms of hydrogen bonds the low affinity (dissociation constant, K_d, in the 0.1–10 mM range) found in the interaction between a monosaccharide and a given lectin. However, it is well known that, in most cases, complex oligosaccharides are several-thousand-fold more potent inhibitors of lectins than monosaccharides.[79,80]

These high binding selectivities towards complex oligosaccharides, first determined by biochemists, are now also explained by X-ray crystallography studies in terms of extended binding sites on a lectin. In addition to some amino acids forming the monosaccharide-binding site, other amino acid residues are involved in additional direct and water-mediated contacts between oligosaccharides and the lectin surface.[78,81,82]

It is very important to know the complex specificity before using a lectin – as a probe in the exploration of cell surface glycoconjugates or as a tool to fractionate various glycoconjugates by affinity chromatography.

3.4.2 Determination of the Complex Specificity of Lectins

The specificity of lectins towards monosaccharides or oligosaccharides of glycoproteins or glycolipids can be determined by inhibition experiments in which monosaccharides or oligosaccharides of known structures are tested for their ability to inhibit either hemagglutination[80] or precipitation of polysaccharides.[83] However, a major drawback of these methods is that they require large quantities of oligosaccharides that are often available only in limited amounts.

A second approach to determine the complex specificity of a lectin is to study the affinity of the immobilized lectin towards complex oligosaccharides.[84,85] In this approach, lectins are first immobilized on insoluble matrices. Small columns containing 2–10 mL of the immobilized lectins are then prepared and equilibrated in an appropriate buffer; the behavior of radiolabeled oligosaccharide or glycopeptides of known structure applied to these columns is then examined.

This second approach is of particular interest because it calls for only small amounts of oligosaccharides and, once the precise specificity of an immobilized lectin is established, it becomes possible to predict the primary structure of glycopeptides or oligosaccharides displaying similar elution profiles.

Specificities of lectins can be also studied using more sophisticated methods including isothermal titration microcalorimetry (ITC)[86] or real-time interaction by surface plasmon resonance with biosensors.[87]

3.4.3 *Specificity of Lectins Towards Complex Oligosaccharides*

From all these studies, important conclusions can be drawn about the carbohydrate-binding specificity of plant lectins. Lectins can interact with internal oligosaccharidic sequences of a glycan. Very few lectins recognize terminal nonreducing monosaccharides on a glycan and most of them recognize internal sequences of oligosaccharides. Lectins identical in terms of monosaccharide specificity can display different complex specificity. Both concanavalin A (Con A) and *Lens culinaris* agglutinin (LCA) display the same monosaccharide specificity for α-Man or α-Glc. However, as shown in Table 3, they display a higher affinity for different *N*-glycosylpeptides and related oligosaccharides. In particular, the presence of a fucose residue at the C-6 position of the GlcNAc residue involved in the *N*-glycosylamine linkage in a biantennary *N*-acetyllactosamine-type glycopeptide enhances the affinity of LCA for this glycan and is an important determinant for the glycan-binding specificity of the lectin.[80,88]

Moreover, a given lectin can recognize very different oligosaccharide sequences. For example, Con A has a strong affinity for oligomannoside type as well as for some hybrid-type glycans and a weaker one for biantennary *N*-acetyllactosamine-type glycans (Table 3).

These complex glycan specificities of plant lectins result from the existence of extended carbohydrate-binding sites on the lectins.

It is also worth noting that different lectins can recognize different saccharide sequences on the same glycan. As these sequences are common to numerous glycoproteins, results obtained with immobilized lectins during a fractionation of glycoproteins or by Western blot analysis of glycoproteins with lectins must be interpreted with caution.

The spatial conformation of glycans may affect their interaction with many lectins. Some lectins, such as LCA or wheat germ agglutinin (WGA) show a stronger affinity for *N*-glycosylpeptides containing the recognized oligosaccharide sequences than for the glycans released from these glycopeptides either by chemical or enzymatical cleavages and still containing the oligosaccharide determinants. This can be explained by the fact that the attachment of a glycan to asparagine imposes on the trisaccharidic core sequence Man(β1–4)GlcNAc(β1–4)GlcNAc(β1-N)Asn a rigid structure that favors the specific recognition of the oligosaccharidic sequences on the glycan by a given lectin.[89] Some lectins such as *Ricinus communis* agglutinin I (RCA I) present a higher affinity for oligosaccharide sequences substituted by sialic acid residues bound in the α-2,6 position of galactose rather than in the α-2,3 position. This can be related to the higher mobility of sialic acid residues around the α-2,6 linkage.[80,90]

However, for *Phaseolus vulgaris* phytohemagglutinins (PHAs) with erythro-agglutinating or leuco-agglutinating activities (E4-PHA and L4-PHA, respectively), this higher mobility of the sialic acid residues around the α-2,6 linkage can mask the internal oligosaccharidic determinants. This can explain why sialylated glycans in the α-2,6 position of galactose are not recognized by these lectins, whereas sialylated glycans in the α-2,3 position of galactose interact with them.[91]

The concept of a larger space mobility of oligosaccharide sequences around an α-1,6-glycosidic linkage compared to the higher rigidity imposed by the α-1,3 linkage can explain the higher affinity of some lectins such as LCA or L4-PHA for tri′-antennary *N*-acetyllactosamine-type glycans (Table 3) in which one of the α-Man residues is substituted by the third antennae at the C-2 and C-6 positions, rather than for triantennary glycans containing another α-Man substituted at C-2 and C-4 positions.[88,92]

Due to their extended carbohydrate-binding sites, most lectins will display very precise specificity towards well-defined oligosaccharide sequences belonging to either *N*- or *O*-glycosylproteins. Therefore, classifications of lectins according to monosaccharide specificity must be superseded by classifications taking into account the concept of dominant oligosaccharides as recognized by lectins at either internal or peripheral positions on a glycan. However, a few lectins will present a specificity towards terminal nonreducing dominant monosaccharides.[93–105]

Table 3 lists the specificity of some commonly used lectins towards oligosaccharide sequences belonging to *N*-glycosylproteins.

3.4.4 *Use of Immobilized Lectins for Fractionation of Glycoproteins*

3.4.4.1 Immobilization of Lectins Numerous methods have been proposed for preparing immobilized lectins and many of them are now available from different suppliers (Pharmacia Biotech, E. Y. Laboratories, Sigma Chemical Co, Vector Laboratories). Lectins immobilized to CNBr-activated agarose are the most popular and can be easily prepared at a density of 2–10 mg of lectin per milliliter of settled gel (agarose, Sepharose™ or Ultrogel®) activated with CNBr according to the procedures of March et al.[60] or Kohn and Wilchek.[61]

Immobilization of lectins on polyacrylic-hydrazido-Sepharose™ support according to Wilchek and Miron[62] does not introduce charged groups into the matrix, a major drawback found in lectin affinity gels prepared by activation of Sepharose™ with CNBr.

[b] Sequences in boxes are the minimal oligosaccharide structure necessary for lectin recognition.
[c] DSA, *Datura stramonium* agglutinin.

Immobilized lectins can be prepared with activated agarose containing *N*-hydroxysuccinimide esters which react with amino groups of lectins.[63] These activated gels are available from BioRad as Affi-Gel® 10 or Affi-Gel® 15.

All these gels can be used in low-pressure chromatography with flow rates of 5–20 mL h^{-1}. However, lectins can be also immobilized on activated supports compatible with HPLC (flow rate of 1 mL min^{-1}). This technique combines the high speed and resolution

characteristics of HPLC with the selectivity of biospecific interactions.[106,107]

3.4.4.2 Fractionation of Glycoproteins on Immobilized Lectins Affinity chromatography on immobilized lectins is now widely used to fractionate either soluble or membrane glycoproteins, and many examples have been reviewed elsewhere.[97,108–113] Highlighted here are some particular points which can be useful during such fractionations.

Variations in the amount, as well as in the quality of the lectin immobilized on a gel, represent important factors influencing the binding of glycoproteins. For example, affinity differences are often observed between different commercially available immobilized Con A. This requires the calibration of the lectin column with well-known glycoproteins before using a new batch of immobilized lectin.

Three fractions are generally obtained, reflecting relative affinities of the glycoproteins for the immobilized lectins.

The nonreactive glycoproteins are eluted at the void volume of the column in the equilibration buffer. This fraction, when the exact capacity of the immobilized lectin is not known, must be submitted to a new cycle of absorption and elution on the same column, to be certain that the immobilized lectin was not saturated during the first run. In order to limit nonspecific interactions between glycoproteins and immobilized lectins, equilibration buffers must possess a moderate ionic strength (0.1–1.0 M in NaCl, for example).

The weakly reactive glycoproteins give fraction(s) that are recovered by elution with the equilibration buffer as retarded fraction(s). In this case, the separation of weakly interacting glycoproteins can be obtained by using a long and thin lectin column; this is more efficient than a wider and shorter column containing the same amount of immobilized lectin. The spatial conformations of the native glycoproteins or nonspecific hydrophobic interactions may modulate the accessibility of some glycans to the lectin and can explain the presence of some artefactual weakly reactive fractions. These fractions are absent when the glycoproteins are reduced and alkylated before fractionation on the immobilized lectin.[114]

Strongly reactive glycoproteins are specifically eluted after extensive washing with the equilibration buffer containing the competitive monosaccharide (0.1–0.5 M). After extensive washing with the equilibration buffer, the immobilized lectin can be used again with the same efficiency. Stronger lectin–glycoprotein interactions may result either in very high affinity of the lectin for some oligosaccharidic determinants of a glycoprotein or in the multivalent interactions between the immobilized lectin and a very high density of a saccharidic determinant of the glycoprotein recognized by the lectin (avidity effect). In the particular case of immobilized Con A, the recovery of high-affinity glycoproteins can be improved by raising the temperature of the 0.5 M methyl-α-D-glucoside or α-D-mannoside solution to 37 °C or even 60 °C. However, very often these strong interactions could be reversed only with nonspecific desorption processes which may cause irreversible denaturation of the immobilized lectin. Such nonspecific elutions can be performed by pH changes with either 20 mM acetic acid or diaminopropane solutions or with 0.02–0.1 M borate buffers (pH 8.0), without denaturation of the lectin.

High-yield recovery can also be obtained by heating the immobilized lectin–glycoprotein complex for 3 min at 100 °C in buffer containing 5% (w/v) sodium dodecyl sulfate (SDS) and 8 M urea, but with irreversible inactivation of the lectin.

The sequential use of immobilized lectins, with different and well-defined specificities towards saccharidic determinants, can be applied to fractionate complex mixtures of glycoproteins into classes depending on their affinities for the different lectins. Immobilized Con A, LCA, and WGA are the most commonly used.

When lectin affinity chromatography is used to fractionate membrane glycoproteins, the most important problem is the stability of the immobilized lectin in the detergent solution utilized for membrane protein extraction. This detergent must be present during all further purification steps of the solubilized membrane glycoproteins. However, this detergent may dissociate the lectin into subunits or change their active conformation. As shown by Lotan et al.,[115] nonionic detergents such as Triton® X-100 at 0.1% concentration in the running buffer remain the most compatible with lectin affinity chromatography of membrane glycoproteins.

3.4.4.3 Limitations of Lectin Affinity Chromatography in Purification of Glycoproteins Affinity chromatography on immobilized lectins rarely permits the purification of a given soluble or membrane glycoprotein from complex mixtures in a single step. This method usually fractionates glycoproteins into different classes containing similar glycans. As different lectins will be able to recognize different saccharidic sequences, but belonging to the same glycan, sequential affinity chromatography on different immobilized lectins will not improve the fractionation significantly.

However, a few membrane or soluble glycoproteins have been isolated in one step from complex mixtures by lectin affinity chromatography. For example, immobilized WGA allows the purification of either glycophorin, the major human erythrocyte membrane glycoprotein,[116] or the insulin receptor[117] in a single step. Laminin, a major

component of basement membrane, can be purified in one step on an immobilized *Griffonia simplicifolia* agglutinin I (GSA I-B4) lectin column.[118]

Human IgA1 and IgD can be isolated in one step from human sera on an immobilized *Artocarpus integrifolia* lectin (Jacalin) column which strongly interacts with the *O*-glycosidically linked Gal(β1–3)GalNAc determinants present in the hinge region of these glycoproteins.[119–122]

α-2 Macroglobulin from human sera is the only glycoprotein with oligomannosidic glycans recognized and eluted with a 0.1 M methyl-α-D-mannoside solution from an immobilized *Galanthus nivalis* mannose-specific lectin, isolated from the snowdrop bulb.[123] However, lectin affinity chromatography usually fractionates glycoproteins into different classes containing similar carbohydrate determinants. Nevertheless, when a given glycoprotein can be purified in a first step from other contaminating glycoproteins, either by conventional biochemical procedures or by immunoaffinity chromatography, lectin affinity chromatography represents a very powerful tool with which to unravel the glycan microheterogeneity inside this glycoprotein.[124]

3.5 Characterization of Glycoprotein Glycosylation

3.5.1 Glycan Detection Kits

Protein glycosylation can be easily and sensitively detected using different detection systems based on immunological labeling of glycoproteins on blots.[125–128] The procedures are based on oxidation of the adjacent hydroxyl groups of the monosaccharide constituents to aldehyde by mild periodate treatment and subsequent derivatization of the resultant aldehyde groups with either biotin or digoxigenin (DIG) via a hydrazide group. Biotin or DIG can be subsequently detected using either streptavidin or antidigoxigenin – alkaline phosphatase conjugate. An adaptation of the method consists in using biotin or DIG-labeled lectins, specific to the different constituent monosaccharides.

These methods are commonly used as a first step to assess both the occurrence and nature of glycans.

3.5.2 Detection of Glycoproteins with Lectins after Separation by Polyacrylamide Gel Electrophoresis

The high resolving power of polyacrylamide slab gel electrophoresis either under native or denaturing conditions[129] or two-dimensional gel electrophoresis combining isoelectric focusing and SDS–polyacrylamide gel electrophoresis[130] allows excellent separations of protein and glycoprotein mixtures. These glycoproteins can be detected with lectins of well-defined specificity either by direct incubation of the gels with lectins or by incubation of the electrophoretically separated glycoproteins transferred onto various immobilizing matrices with lectins.

3.5.2.1 Direct Application of Lectins to Polyacrylamide Gels

Use of Radioiodinated Lectins.[131] After electrophoresis, the slab gel slices are fixed in solution with or without 0.1% Coomassie brilliant blue and washed in a destaining solution containing 7.5% methanol and 7.5% acetic acid in water. After equilibration in Tris-buffered saline (TBS) (0.05 M Tris · HCl, pH 7.5; 0.15 M NaCl; 0.1% NaN_3), gel slices are put in a flat, humidified plastic box, overlaid with a radioiodinated lectin diluted in the equilibration buffer to $0.1–2.0 \times 10^7$ cpm mL^{-1} and incubated for 1–20 h.

After incubation, unbound lectin is washed out in several changes of equilibration buffer. Gel slices are then dried out and the lectin-reactive glycoproteins visualized by autoradiography.

In the overlay method, there is only binding of the radioiodinated lectin to glycoproteins on the overlaid face of the gel. Total immersion of the gel slices in the lectin solution will label both gel faces, but more lectin solution will be necessary.

For a given lectin, parallel gel slices must be incubated and washed in the presence or absence of 0.1 M competitive monosaccharide to detect any nonspecific binding.

On a gel slice, different glycoproteins can be revealed by a lectin because they possess the same oligosaccharide determinant recognized by the lectin. A single glycoprotein on a gel can be revealed by several lectins because of the possible glycan microheterogeneity of this glycoprotein, but also because different saccharide sequences belonging to a single glycan can be recognized by different lectins.

Use of Peroxidase-labeled Lectins. After electrophoresis, separated glycoproteins can be also reacted with peroxidase-coupled lectins and detected by color development of the enzyme reaction.[132] Lectins can be easily coupled to horseradish peroxidase and many peroxidase-coupled lectins are commercially available. However, some lectins, such as Con A, can be used without any coupling procedure with peroxidase because of their multivalency and of their great affinity for the N-linked glycans of horseradish peroxidase. In the first step, the lectin will bind to the separated glycoproteins on the gel and, in the second step, the glycoprotein-bound lectin will bind to horseradish peroxidase, which will be visualized by the chromogenic reaction with 3,3′-diaminobenzidine as the substrate.

3.5.2.2 Detection of Glycoproteins after Transfer Onto Immobilizing Matrices The transfer of electrophoretically separated proteins and glycoproteins onto immobilizing matrices was first described in 1979 by Renart et al.[133] and Towbin et al.[134] Since then, protein blotting has become the method of choice for detecting and characterizing proteins in complex mixtures.[135,136]

After electrophoresis, the separated proteins and glycoproteins are transferred onto different immobilizing matrices under conditions that maintain the electrophoretic pattern. Electrotransfer is generally preferred to capillary transfer because of the increased speed and the improved resolution of the bands. Many immobilizing matrices have been described but the most popular are the cellulose nitrate (CN) and the microporous polyvinylidene difluoride (PVDF) membranes on which transferred proteins are strongly bound by interfacial (hydrophobic) interactions.

Transfer conditions must be defined with care. The composition of the transfer buffers, with or without methanol which promotes hydrophobic binding by stripping SDS from proteins and with or without SDS which increases the elution of high-molecular-weight proteins from the gel as well as the running conditions, depends on the proteins to be transferred.

After the transfer of proteins to immobilizing matrices, all the unoccupied potential binding sites of the matrices must be blocked to avoid unspecific binding of the detecting molecules. Electrotransferred glycoproteins can be visualized by incubation of the matrices with radioiodinated lectins,[137] with biotin-conjugated lectins revealed with avidin-peroxidase, with peroxidase-coupled lectins or with DIG-labeled lectins[138] revealed with anti-DIG antibodies conjugated either to alkaline phosphatase, to horseradish peroxidase or labeled with fluorescence markers.

In particular, the detection of glycoproteins on blots with DIG-labeled lectins represents a very sensitive method based on the use of the plant steroid DIG as a hapten which will be detected by antibodies (anti-DIG) with high affinity towards this hapten. DIG-labeled lectins as well as DIG antibody (Fab fragments) conjugated with alkaline phosphatase are available from Boehringer Mannheim (Mannheim, Germany).

Together with blots with electrotransferred glycoproteins, dot blots, prepared by spotting on nitrocellulose membrane glycopeptide-containing fractions obtained by different chromatographic methods, can be revealed by the DIG–lectin/anti-DIG–alkaline phosphatase system.

It is also noteworthy that, as electrotransferred glycoproteins are strongly bound on nitrocellulose or PVDF membranes, treatment of the immobilized glycoproteins with various endo- or exoglycosidases of known specificities, in combination with DIG–lectins of well-defined specificities, can provide structural information on the glycan moieties using minute amount of glycoproteins. However, reference glycoproteins with well-characterized glycans must then be included in the analyzed membrane in order to verify the efficiency of either the enzymatic treatment(s) and/or the lectin specificity.

3.5.3 Crossed Affinoimmunoelectrophoresis of Glycoproteins

Crossed affinoimmunoelectrophoresis (CAIE) combines the interaction between a lectin and glycoproteins in the first-dimension electrophoretic step with crossed electrophoresis into an antibody-containing gel in the second dimension.[139] This sensitive technique can give important information about the interaction between a given lectin and the glycoprotein to be purified because a good correlation is generally observed between results obtained by CAIE and by affinity chromatography on the immobilized lectin.

Above all, the method rapidly reveals the glycan microheterogeneity of the glycoprotein to be purified. This method can also be used for the characterization of membrane glycoproteins solubilized in nonionic detergents because both lectin–membrane glycoprotein interactions and antigenicity of membrane glycoproteins are not affected by nonionic detergents such as Triton® X-100.[140,141]

Finally, determination of glycan microheterogeneity of serum glycoproteins by CAIE can be used for a rapid and discriminating diagnosis of various pathological conditions.[142]

4 ISOLATION AND CHARACTERIZATION OF GLYCOPEPTIDES AND GLYCANS

4.1 Proteolytic Digestion of Glycoprotein

In an individual glycoprotein each attachment site frequently accommodates different glycans generating a set of glycoforms. Examination of the glycosylation site heterogeneity requires the proteolysis of the glycoprotein to obtain glycopeptides of different size, which may be HPLC separated or purified and subsequently analyzed by MS. Each individual glycopeptide will contain a unique peptide sequence and a single oligosaccharide chain.

The choice of the protease will determine the number of peptides (or glycopeptides) produced and the length of the peptidic chain (directly related to the hydrophobicity of the glycopeptides) and for this reason will considerably influence the choice of the HPLC elution conditions.

4.1.1 Pronase Digestion

Pronase, which is a mixture of endopeptidases with broad specificity, can be used to obtain glycoasparagines or glycopeptides with a very short peptide chain. After purification, the structure of the glycan moieties can be established either directly or after their release by chemical or enzymatic methods.

4.1.2 Tryptic and Chymotryptic Digestion

In order to minimize the peptide heterogeneity of the glycopeptide, the enzymes of choice will be the highly specific proteases such as trypsin or chymotrypsin. Proteolytic hydrolysis may be performed either on native glycoproteins or after reduction and alkylation which generally produces a better substrate for protease digestion.

Trypsin, chymotrypsin or endoproteinase Glu C (*Staphylococcus aureus* V8 protease) are used when a longer polypeptide chain is required or when it appears necessary to access the different glycan structure to each of the glycosylation sites present on the polypeptide chain.

4.2 Methods for Glycan Release

As a detailed structure of individual glycans cannot be achieved directly on the native glycoprotein, for a complete structural study the glycans must be released from the glycoprotein either by chemical or enzymatic hydrolysis.

4.2.1 Chemical Release of Glycans

As previously mentioned, glycans can be covalently linked to the peptidic backbone through *O*- or *N*-glycosidic linkages. These two fundamental types of linkages present different susceptibility to alkaline hydrolysis. The O-linkage is easily cleaved in diluted sodium hydroxide solutions (0.05–0.1 M) at 37 °C for 48 h[143,144] in the so-called β-elimination reaction. Alkaline treatment is generally achieved in the presence of a reductive agent such as sodium borohydride ($NaBH_4$) in order to avoid further degradation by a peeling reaction of released oligosaccharides. For that reason, *O*-glycans are released from the glycoprotein as oligosaccharide-alditols.

The N-linkage is quite stable during the β-elimination procedure and *N*-glycans are released as glycopeptides. Cleavage of *N*-glycans requires a strong alkaline agent such as hydrazine.[145] The hydrazinolysis procedure is commonly used for releasing *N*-glycans.[146–149] This is then a three-step procedure including the hydrazine treatment, the *N*-re-acetylation of hexosamines and sialic acids, and the cleavage of resulting hydrazones. *N*-Glycans are released as free oligosaccharides, having the di-*N*-acetyl-chitobiose unit at their reducing end. *O*-Glycans can be partially released using mild reaction conditions.[149] It should be mentioned that both procedures lead to the destruction of the polypeptide backbone.

4.2.2 Enzymatic Release of Glycans

Release of glycans from *N*-glycosylproteins can be achieved by two kinds of enzymes, namely *endo-N*-acetyl-β-D-glucosaminidases and peptide-*N*-glycosidases.

4.2.2.1 Endo-N-*Acetyl-β-D-Glucosaminidases (EC 3.2.1.96; Mannosyl-glycoprotein 1,4-*N*-Acetamido-deoxy-β-D-glycohydrolases)* This family of enzymes hydrolyses the di-*N*-acetylchitobiose unit common to all the *N*-glycans[150] according to Equation (1):

$$\begin{aligned}&(R)\text{-GlcNAc}(\beta1-4)\text{GlcNAc}(\beta1-\text{N})\text{Asn-}(\text{X})_n\\&\quad\longrightarrow (\text{R})\text{-GlcNAc} + \text{GlcNAc-Asn-}(\text{X})_n\\&\quad\text{oligosaccharide} + \text{protein}\end{aligned} \qquad (1)$$

- Endo H, isolated from *Streptomyces plicatus*,[151] and endo F1, from *Flavobacterium meningosepticum*,[152] hydrolyze both high-mannose-type and hybrid-type glycans. These enzymes represent useful tools to discriminate between high-mannose and lactosaminic-type glycoproteins.
- Endo B, isolated from *Sporotrichum dimorphosporum*,[153] and endo F2, from *Flavobacterium meningosepticum*,[152] act both on high-mannose and complex glycans.

Generally glycoproteins are denatured prior to the enzymatic hydrolysis; nevertheless *endo*-β-*N*-acetyl-hexosaminidases are able to deglycosylate native glycoproteins and may be employed for the study of glycan functions inside an individual glycoprotein.

*4.2.2.2 Peptide-*N*-glycosidase (EC 3.5.1.52; Peptide-*N*^{4}-(N-acetyl-β-glucosaminyl) Asparagine Amidase)* Peptide-*N*-glycosidase, also called *N*-glycanase® is able to split the monosaccharide–peptide linkage removing the complete glycan moiety of the molecule (Equation 2):

$$N\text{-glycosyl-Asn-protein} \xrightarrow{\text{Glycanase}} \text{glycan} + \text{Asp-protein} + \text{NH}_3 \qquad (2)$$

The enzyme cleaves all types of glycans and the reaction proceeds unless the peptide part is restricted to the sole asparagine residue. The enzyme is isolated from *Flavobacterium meningosepticum*[152] (peptide-*N*-glycosidase F). The enzyme is now cloned and

expressed in *Escherichia coli*.[154] Another peptide-*N*-glycosidase (peptide-*N*-glycosidase A) has been isolated from almond emulsin.[155] This enzyme is able to cleave glycans bearing an α-1,3-fucose attached to the first *N*-acetylglucosamine linked to asparagine as found in plant *N*-glycosylproteins.

4.3 Fractionation of Glycopeptides and Glycans

4.3.1 Use of Immobilized Lectins for Fractionation of Glycopeptides and Oligosaccharides

Even though the purification and fractionation of glycoproteins by lectin affinity chromatography is encumbered with some limitations, this method represents a powerful tool for the fractionation of glycopeptides and glycans. Nonspecific interactions often observed between glycoproteins and immobilized lectins, or strong interactions resulting from the presence on a glycoprotein of a high density of a particular saccharide determinant, are absent or very rare in the case of glycans or glycopeptides. These compounds are thus fractionated on the basis of a true affinity chromatography. Consequently, this implies, even more than in glycoprotein fractionations, a very precise knowledge of the exact specificities of the immobilized lectins to be used. Under these circumstances, it often becomes possible to predict the primary structure of lectin-reactive glycopeptides or glycans.

Many fractionation schemes of glycopeptides or glycans, obtained from soluble or membrane-bound glycoproteins, have been proposed.[95–105,156–159]

4.3.1.1 General Comments Before using a new batch of immobilized lectin or after repeated use of a lectin column which may lead to a decrease in its binding capacity, calibration of the lectin column with well-defined glycopeptides or glycans should be performed. Standard glycopeptides or mixtures of glycopeptides to be fractionated can be *N*-[^{14}C]- or [^{3}H]-acetylated[160] to help follow the lectin column performance. Standard oligosaccharides or mixtures of glycans to be fractionated, released from glycoproteins or glycopeptides either by chemical or by enzymatic cleavages, can be labeled at the terminal reducing GlcNAc residue by reduction with [^{3}H]-sodium or potassium borohydride.[161]

Most lectin columns equilibrated in PBS containing 0.02% sodium azide can be run at room temperature (20 °C) but should be stored at 4 °C between consecutive runs. Most lectins are less efficient at 37 °C than at room temperature or even at 4 °C.[101,115] The degree of separation of weakly reactive glycopeptides or glycans may depend on the geometry of the lectin column. A better separation of these compounds is generally obtained with a long and thin column rather than with a wider column containing the same amount of immobilized lectins.

When the exact capacity of a lectin column is not known, the unretained fraction must be recycled on the regenerated column. For example, commercially available Con A–Sepharose™ 4B from Pharmacia Biotech is able to bind 50–75 μg per milliliter of gel of biantennary *N*-glycosylpeptides.

Most immobilized lectins have the same affinity for *N*-glycosylpeptides and for glycans released from them either by chemical or enzymatic cleavages. However, *N*-*N*′-diacetylchitobiose-Asn inner core is an important determinant for binding to immobilized LCA or WGA, and glycans without the asparagine residue or a small peptidic sequence do not interact with these immobilized lectins. This is an important point to consider in a fractionation procedure to be used because the discriminating power of an immobilized LCA–or WGA–Sepharose™ column is considerable and cannot be neglected.

As previously described for glycoproteins, sequential use of immobilized lectins with different and well-defined specificities can fractionate complex mixtures of glycopeptides or glycans into homogeneous families. Generally, lectins with affinity for internal saccharide sequences are used first in the fractionation, whereas immobilized lectins with a specificity towards terminal oligosaccharide-dominant sequences or terminal nonreducing monosaccharides are used later.

4.3.1.2 Fractionation of N*-Glycosylpeptides or Related Glycans on Immobilized Lectins with Affinity for Internal Oligosaccharidic Sequences*

Affinity Chromatography on Immobilized Concanavalin A and Lens culinaris Agglutinin. Figure 8 presents the structures of *N*-glycosylpeptides or related glycans which can be found in the three fractions recovered from an immobilized Con A column as well as in the six fractions resulting from a subsequent affinity chromatography of *N*-glycosylpeptides on an LCA–Sepharose™ column. From this figure, it clearly appears that the α-1,6-linked fucose residue is an important determinant for the binding of *N*-glycosylpeptides and that affinity chromatography on immobilized LCA is a valuable tool with which to fractionate glycopeptides into α-1,6-fucosylated and nonfucosylated types. Only *N*-glycosylpeptides can be bound on immobilized LCA. So, glycans released from *N*-glycosylpeptides either by hydrazinolysis or by enzymatic cleavage are eluted at the void volume of the lectin column.

Immobilized *Vicia faba* and *Pisum sativum* lectins interact also with some α-1,6-fucosylated *N*-glycosylpeptides.

Figure 8 Interaction of *N*-glycosylpeptides with immobilized Con A and LCA (NBF = nonbound fraction, WBF = weakly bound fractions, BF = bound fractions, SBF = strongly bound fractions).

However, their affinity is weaker, so that the fractionation into the two classes is obtained with only the equilibration buffer.

Affinity Chromatography on Other Lectins with a Specificity for Internal Saccharidic Sequences. Other immobilized lectins with a specificity for internal saccharide sequences can also be used to subfractionate *N*-glycosylpeptide families obtained by affinity chromatography on immobilized Con A and LCA.

As shown in Table 3, *Phaseolus vulgaris* isolectin E4 (E4-PHA) interacts with bisected bi- and triantennary *N*-acetyllactosamine-type glycopeptides or related glycans, and *Phaseolus vulgaris* isolectin L4 (L4-PHA) interacts with asialotri′- and tetraantennary *N*-acetyllactosamine-type glycopeptides or related glycans, containing the dominant pentasaccharidic sequence Gal(β1–4)GlcNAc-(β1–2)[Gal(β1–4)GlcNAc(β1–6)]Man. The two immobilized lectins can be used to subfractionate glycopeptide fractions containing these oligosaccharidic determinants previously isolated by a sequential affinity chromatography on immobilized Con A–and LCA–sepharose™.

Immobilized WGA can be used to fractionate some hybrid-type *N*-glycosylpeptides which are bound on a WGA–Sepharose™ column, and to a lesser extent bisected biantennary *N*-acetyllactosaminic-type glycopeptides which are only retarded on such a column.[162,163] Linear poly(*N*-acetyllactosamine) as well as branched poly(*N*-acetyllactosamine)-type glycopeptides or glycans are also recognized with high affinity by immobilized WGA.[164–166] Immobilized WGA also interacts with glycopeptides having a high density of *O*-glycosidically linked sialyl oligosaccharides.[167,168]

4.3.1.3 Fractionation of N-*Glycosylpeptides or Related Glycans on Immobilized Lectins with Affinity Directed Towards Terminal Oligosaccharide-dominant Sequences*

*Lectins with a Specificity for Poly(*N*-acetyllactosamine)-type Glycans.* Immobilized pokeweed mitogens,[169] immobilized *Lycopersicon esculentum* agglutinin (tomato lectin),[95,170] or immobilized DSA[171] represent useful tools for the fractionation of *N*-acetyllactosamine-type glycans with repeating *N*-acetyllactosamine sequences.

Lectins with a Specificity for Terminal N-*Acetyllactosamine Sequences.* Immobilized RCA I and RCA II (*Ricinus communis* agglutinin II) present distinct oligosaccharide specificities and the combined use of these two lectins allows the fractionation of *N*-acetyllactosamine-type glycans according to the nature and the linkage of their terminal sugar moieties.[90] Like immobilized RCA I, immobilized RCA II strongly interacts with *N*-acetyllactosamine-type oligosaccharides possessing terminal β-1,4-linked galactose residues. However, immobilized RCA II can also strongly interact with *N*-acetyllactosamine-type oligosaccharides containing nonreducing β-1,4-linked GalNAc residues. Moreover, whereas immobilized RCA I has a weak affinity for *N*-acetyllactosamine-type oligosaccharides with one or two terminal β-1,3-linked galactose residues, immobilized RCA II strongly binds these glycans which can be eluted with a GalNAc solution.

The carbohydrate-binding specificity of four *Erythrina* (*E. cristagalli, E. latissima, E. corallodendron, E. lysistemon*) lectins is also directed towards unmasked terminal *N*-acetyllactosamine sequences.[172] As for immobilized RCA I, the interaction of *N*-acetyllactosamine-type glycans with immobilized *Erythrina* lectins depends on the number of terminal *N*-acetyllactosamine sequences.

Lectins with a Specificity for Sialylated N-*Acetyllactosamine Sequences.* The immobilized lectin *Sambucus nigra* agglutinin I (SNA I), isolated from the bark of elder, recognizes oligosaccharides, glycopeptides, or glycoproteins with terminal NeuAc(α2–6) Gal/GalNAc sequences which are bound and can be eluted from the lectin column with a lactose solution. However, asialo derivatives as well as those containing NeuAc(α2–3)Gal/GalNAc sequences do not interact with immobilized SNA I.[173]

Immobilized *Maackia amurensis* leukoagglutinin (MAL) binds with high-affinity *N*-acetyllactosamine-type glycopeptides containing terminal NeuAc(α2–3)Gal-(β1–4)GlcNAc sequences. Conversely, asialoglycopeptides as well as glycans with terminal NeuAc(α2–6)Gal-(β1–4)GlcNAc sequences do not interact with the immobilized leukoagglutinin.[174]

Therefore, immobilized MAL and SNA I are two interesting lectins, which can be sequentially used to fractionate sialylated glycans on the basis of their sialic acid linkages and according to the number of sialic acid residues they contain.

4.3.1.4 Subfractionation of N-*Glycosylpeptides on Immobilized Lectins with a Specificity Directed Towards Terminal Nonreducing Dominant Monosaccharides*

Lectins Recognizing Nonreducing Mannose Residues. The immobilized *Galanthus nivalis* agglutinin (GNA),[175] *Narcissus pseudonarcissus* agglutinin (NPA),[176] *Hippeastrum hybrida* agglutinin (HHA)[176] isolated from snowdrop, daffodil or amaryllis bulbs, as well as

Bowringia milbraedi agglutinin (BMA)[177] isolated from the seeds of the Nigerian legume *Bowringia milbraedi* provide interesting tools for the analysis and fractionation of glycoproteins or glycopeptides containing oligomannosidic-type glycans.

Lectins Recognizing Terminal Nonreducing N-*Acetylgalactosamine and Galactose Residues.* Seeds of *Griffonia simplicifolia* contain five tetrameric isolectins composed of two subunits A and B.[178] The carbohydrate-binding specificity of the two subunits differs significantly. The A4 tetrameric isolectin GSA I-A4 recognizes terminal nonreducing α-linked *N*-acetylgalactosamine residues, whereas the B4 isolectin (GSA I-B4) has strict specificity towards terminal nonreducing α-linked galactose residues.

Immobilized GSA I isolectins can be used to isolate either α-Gal-containing glycopeptides[179] or α-GalNAc-containing glycopeptides.[180]

Glycopeptides containing the GalNAc(β1–4)GlcNAc sequence in their outer branch moieties bind with high affinity to immobilized *Wisteria floribunda* agglutinin.[181]

Lectins Recognizing Terminal Nonreducing N-*Acetyl Glucosamine Residues.* Immobilized *Griffonia simplicifolia* agglutinin II (GSA II)[182] as well as immobilized *Psathyrella velutina* agglutinin, a lectin isolated from the fruiting bodies of the mushroom *Psathyrella velutina*[183] represent useful tools for the detection and fractionation of glycoproteins, glycopeptides or glycans with terminal nonreducing GlcNAc residues.

Fucose-binding Lectins. Immobilized *Lotus tetragonolobus* agglutinin (LTA) displays strong affinity for poly-*N*-acetyllactosamine-type *N*-glycosylpeptides containing high amounts of fucose linked α-1,3 to *N*-acetyllactosamine residues within the linear repeating disaccharide 3-Gal(β1–4)GlcNAc(β1–3)$_n$ (Lewis^x antigenic blood group). These glycopeptides are bound to an immobilized LTA column and can be eluted with a fucose solution.[184]

Another immobilized fucose-binding lectin, isolated from fruiting bodies of the mushroom *Aleuria aurantia*, represents a very valuable tool for the resolution of glycopeptides and glycans embellished with different Fuc substituents.[185,186]

4.3.1.5 Fractionation of O-*Glycosylpeptides Using Immobilized Lectins* A large panel of lectins with well-defined specificities towards oligosaccharidic sequences belonging to *N*-glycosylproteins is now available for the study of glycan microheterogeneity or for fractionation of *N*-glycoproteins, glycopeptides, or related glycans. However, very few applications can be found in the literature of similar studies using lectins specifically recognizing *O*-glycosidically linked glycans.

Nevertheless, by inhibition of hemagglutination or by quantitative precipitation, many lectins were shown to bind to mucin-type oligosaccharides.[75,187]

The carbohydrate-binding specificities of five of these lectins (ABA I (*Agaricus bisporus* agglutinin I), PNA (*Arachis hypogaea* agglutinin), BPA (*Bauhinia purpurea* agglutinin), SBA (soybean agglutinin) from *Glycine max*, and VVA B4 (*Vicia villosa* agglutinin B4)) has been studied by affinity chromatography of mucin-type glycopeptides and related oligosaccharides of known structures.[188]

Another lectin, jacalin, isolated from jackfruit (*Artocarpus integrifolia*) with a high affinity for the T-antigen Gal(β1–3)GalNAc[189] represents a useful tool for the analysis and fractionation of glycoproteins containing *O*-glycosidically linked glycans[190] as well as for the fractionation of *O*-glycosylpeptides or related oligosaccharide-alditols.[191,192]

4.3.2 High-performance Liquid Chromatography Separation of Oligosaccharides and Glycopeptides

4.3.2.1 Reversed-phase High-performance Liquid Chromatography of Glycopeptides Fractionation of glycopeptides released by proteolytic cleavage may be performed by hydrophobic binding and reversed-phase chromatography.

Separation of glycopeptides is generally achieved on C_{18} columns (octadecylsilyl silica) or C_8 columns (octasilyl silica). The essential criterion responsible for separation is the interaction of the packing with polar materials. Reversed-phase high-performance liquid chromatography (RPHPLC) will allow separation on the basis of peptide hydrophobicity. Modification of the amino terminus with tyrosine increases this hydrophobicity.[193] Under some elution conditions the degree of sialylation of glycopeptides can influence the separation. In the general procedure using aqueous solutions or solvents of medium polarity (acetonitrile), the more polar species elute first and then, as the polarity decreases, the tightly bound more hydrophobic species are eluted. When analyzing glycosylation site heterogeneity, an initial separation of glycopeptides according to their peptide structure, but not according to the oligosaccharide(s) structure, is advantageous.[194–196] The site-specific glycopeptides can then be fractionated on the basis of their carbohydrate structure. Glycopeptides separated by RPHPLC may be further studied by MS.

4.3.2.2 High-performance Liquid Chromatography Separation of Oligosaccharides As a result of their extreme structural diversity, oligosaccharides isolated

from glycoproteins are complex mixtures often of closely related isomeric compounds. For this reason HPLC has proved to be of great value in oligosaccharide purification because of the wide range of absorbents and solvent systems available as well as the speed of separation. Glycans can be separated according to different structural parameters such as their size, charge, or composition.[197–199] Some chromatographic systems such as HPAEC (high-pH anion-exchange chromatography) will also be selective for the ring substitution and branching configuration.[200]

Reversed-phase High-performance Liquid Chromatography of Oligosaccharides. Separation of neutral oligosaccharides may be achieved at room temperature on C_{18} octadecyl silane (ODS) RPHPLC columns using either pure water as an eluent or a low acetonitrile concentration (1–5%). As oligosaccharides occur in solution as a mixture of anomers (α, β) a pure oligosaccharide may provide two peaks during the HPLC separation or more generally poorly resolved broad peaks are obtained.

Free nonreduced oligosaccharides released from glycoproteins either by hydrazinolysis or endoglycosidases can be derivatized on their reducing group with an amino group containing fluorescent or ultraviolet (UV) dyes (Scheme 1) by reductive amination reaction.[201,202] This increases the sensitivity of detection and quantities in the picomole range of oligosaccharides can be detected. The resolution by RPHPLC of the derivatized oligosaccharides is also improved. Furthermore, the derivatized oligosaccharides can be directly analyzed by fast atom bombardment mass spectrometry (FABMS) or matrix-assisted laser desorption/ionization mass spectrometry (MALDIMS), the fluorescent or UV probes enhancing the ion intensity. A number of procedures have been described for the derivatization of oligosaccharides, the most popular methods being pyridylamination[203,204] and benzoylation.[205]

Scheme 1 Principal dyes used for tagging oligosaccharides.

Sialylated oligosaccharides are not retained on the C_{18} columns. Separation of sialylated oligosaccharides may be obtained by neutralizing their charges with triethylamine. Elution is made isocratically with triethylamine acetic acid buffer (10 mM, pH 5.0).[206] UV detection is then impossible and carbohydrates are detected using a refractometer. This method has been used for the separation of human milk sialyl oligosaccharides.[206–208] Separation of sialylated compounds is also possible in the derivatized forms.[209]

Elution of oligomers on ODS columns gives a separation with an increased retention time for oligomers with higher M_r values.[210] When oligosaccharides contain both neutral and acetamido sugars, oligosaccharides having a higher acetamido/neutral sugar ratio have a longer retention time because of the relative hydrophobicity of acetamido groups compared with hydroxyl groups. The same hydrophobicity is observed for fucosylated oligosaccharides, which are generally more retained on the column compared with the nonfucosylated form.[211]

If RPHPLC of neutral oligosaccharides is rather limited, separation of derivatized oligosaccharides (pyridylamino, benzoylated) gives a better separation of these compounds according to their molecular size or the nature of constituent monosaccharides (hexosamines, fucose). For these reasons, RPHPLC of derivatized oligosaccharides is used in two-dimensional mapping strategies. These methods are based on parameterization of the contribution of the individual component sugars to the chromatographic behavior of the oligosaccharides. Thus the oligosaccharides are chromatographed on two HPLC columns and their elution volumes are expressed relative to those of standard glucose oligomers.[212–219]

RPHPLC separation of perbenzoylated high-mannose-type oligosaccharides[205,220] allows the separation of positional isomers.

Ion-exchange High-performance Liquid Chromatography.

- Anion-exchange chromatography. Oligosaccharides may be differently charged according to the presence of acidic monosaccharides such as sialic acid, GlcA, or the presence of anionic substituents (sulfate or phosphate groups). Therefore, glycans can be subjected to ion exchange chromatography and separated into neutral, mono- di-, tri-, or tetracharged compounds. Separation of oligosaccharides according to the number of charges generally constitutes the first step in glycan separation. Either strong or weak anion exchangers can be used for the separation of oligosaccharides.[221]

  Sialylated and sulfated oligosaccharides can be separated on a Micropak® AXS (30 cm × 4.6 mm) column (Varian)[222] and acidic oligosaccharides have

been separated on a Mono-Q® HR 5/5 (50 cm × 5 mm) column (Pharmacia).[223]

- HPAEC of oligosaccharides. The recent introduction of HPLC using pellicular ion-exchange resins under high-pH conditions and detection of sugars with pulsed amperometric detection (PAD) has simplified the separation and analysis of both mono- and oligosaccharides.[200,224] The method may be used for analytical (i.e. for mapping oligosaccharides released from glycoproteins) or for preparative purposes, when it constitutes the final step in oligosaccharide purification. HPAEC has been applied with success in the separation of glycans originating both from *N*-glycosylproteins and mucins as well as from glycolipids.[224,225] The high resolving power of HPAEC and the high sensitivity of pulsed amperometry detection has allowed for a simple one-step procedure for profiling the total N-linked oligosaccharide released from a glycoprotein by either endoglycosidase digestion or hydrazinolysis. The advantages of HPAEC/PAD are its ability to separate underivatized oligosaccharides and its sensitivity (10 pmol). The high resolution obtained with commercially available columns makes possible the profiling of any given glycoprotein. Isomeric forms differing in only a single linkage or in branch position of one residue may be resolved by HPAEC.

  The principle of the method lies in the fact that carbohydrates – which are polyhydric compounds – may be considered to be weak acids, thus in basic solution oligosaccharides form negatively charged oxyanions that will interact on strong anion-exchange columns.

  Predicting the elution order of oligosaccharides is largely empirical because different factors affect the formation of oxyanions, such as the number and nature of the monosaccharides, linkage, branch location, hydrophobicity, or steric conformation. However, the following observations hold:

  - The retention volume increases with the degree of polymerization.
  - Oligosaccharide-alditols have shorter retention times in comparison to nonreduced oligosaccharides.
  - Oligosaccharides with a fucose (α1–6)-linked to the chitobiosyl core elute earlier than nonfucosylated oligosaccharides.
  - Sialylated oligosaccharides with (2–3)-linked NeuAc are more retained than those with (α2–6)-linked NeuAc.
  - Elongation with an additive Gal(β1–4)GlcNAc sequence decreases the retention time.
  - Oligosaccharides with a Gal(β1–3)GlcNAc unit elute later than their counterparts with a Gal(β1–4)GlcNAc sequence.
  - Branching tends to shorten the retention time.

Adsorption High-performance Liquid Chromatography of Oligosaccharides.

- *Silica adsorption HPLC*. Adsorption or normal-phase chromatography relies on the surface hydroxyl groups of silica which can interact with solutes, thereby allowing separation according to the different strengths of interactions. This method is generally used for the separation of derivatized oligosaccharides with a low degree of polymerization using nonaqueous eluents.
- *Hydrophobic HPLC on porous graphitized carbon*. These types of columns are now commercially available from Oxford Glycosystems (Glycosep® H). The columns are run in the same eluents as RPHPLC (aqueous/organic solvents in the presence of 0.05% trifluoroacetic acid (TFA)). Separation is based on the interactions of the hydrophobic areas of glycopeptides and oligosaccharides with the carbon surface.[226] The method may be used for the separation of derivatized oligosaccharides and provides separation of both neutral and sialyl oligosaccharides.

Size-partition High-performance Liquid Chromatography of Oligosaccharides.

- *Ion-suppression Amine-adsorption HPLC*. This method provides for the separation of neutral or negatively charged oligosaccharides, according to their size, on amine columns. Whereas neutral oligosaccharides can be eluted from the column by a liner gradient of acetonitrile/H_2O by increasing the proportion of water,[227] anionic oligosaccharides interact with the solid phase and cannot be eluted.

  The ionic interactions of such negatively charged oligosaccharides can be suppressed by including 3% (v/v) acetic acid titrated to pH 5.5 with triethylamine in the mobile phase. This modification of the mobile phase allows oligosaccharides to be eluted in order of size. Nevertheless, it should be mentioned that separations by ion-suppression amine-adsorption HPLC are sensitive to the identity of the anionic moiety, in that oligosaccharides containing (α2–3)-linked sialic acid elute earlier than those containing (α2–6)-linked sialic acid,[228] and to the branching pattern.[229]
- *Bonded-phase HPLC*. The most frequently used systems for the separation of oligosaccharides are those using chemically bonded phases which fractionate

material on the basis of their relative affinities for the mobile phase and the bonded phase. Supports containing cyano, diol or aminopropyl[230–233] phases may be used. This type of HPLC not only provides size separation of the oligomers, but also of isomers differing in the anomericity or their branching pattern.

- *Gel-permeation HPLC*. Gel-filtration medium-pressure HPLC of oligosaccharides may be realized on noncompressible matrices such as hydroxylated polyether-based matrices (TSK™-PW or TSK™-HW, from Merck). Nevertheless, the separations are inferior to those currently obtainable by other HPLC techniques and consequently little emphasis is placed here on gel-permeation HPLC of oligosaccharides. This method is generally limited to the desalting of oligosaccharide fractions. However, it should be mentioned that Oxford Glycosystems have developed a method of oligosaccharide analysis based on the sequential degradation by exoglycosidases followed by gel-permeation chromatography of the enzymatic hydrolysate. Each oligosaccharide gives a specific pattern calibrated in glucose units obtained by the reagent array analytical method (RAAM).[234]

High-performance Affinity Chromatography of Oligosaccharides. The introduction of macroporous silica as a solid support for affinity columns has improved their resolution and shortened their analysis time.[235,236] This method is based on weak ligand–ligate interactions at high concentrations of bound ligand on rigid particles approximately 10 μm in diameter. Use of monoclonal antibodies[237] or lectins as ligands[238] allows excellent chromatographic separation of oligosaccharides.

4.3.3 Electrophoretic Separation of Glycans and Glycoforms

4.3.3.1 Electrophoretic Separation of Glycans and Glycoforms by Capillary Electrophoresis During the last years capillary zone electrophoresis (CZE) has become a good alternative and rapid procedure for profiling both glycans and glycoforms.[239–242] The procedure is based on the differential migration of solutes through a narrow-bore fused-silica capillary. Charged compounds including sialylated, sulfated, and phosphorylated oligosaccharides migrate in an applied electric field at neutral pH. Neutral sugars can be given a charge by simply adjusting the pH of their environment (high pH), complexation with borate-containing buffers, or conjugation with charged species.[243–246]

A major limitation of using CZE for carbohydrate analysis has been the absence of sensitive detection methods. UV detection has been used for both underivatized and derivatized carbohydrates but it has limited detection sensitivity.[247] In contrast, fluorescence detection is easily adapted after conjugation of carbohydrates to different fluorophores, and charged fluorescent tags such as 7-amino-1,3-naphthalene disulfonic acid are commonly used.[248] Laser sources are capable of focusing light in small capillaries and thus give increased sensitivity of detection. Detection can also be achieved by PAD.[249]

In addition to oligosaccharides, CZE provides efficient separation of glycoforms of a single glycoprotein, according to the occupancy of the different glycosylation sites. This method is routinely used for control of the glycosylation pattern of recombinant glycoproteins.[250–253]

4.3.3.2 Fluorophore-assisted Carbohydrate Electrophoresis Acidic oligosaccharides can be separated by polyacrylamide gel electrophoresis (20–40% slab gels) according to their charge. For that reason, only charged compounds (e.g. those containing sialic acid, uronic acids or charged *O*-glycans such as sulfate or phosphate groups) can be analyzed by electrophoresis. To overcome this limitation of the FACE technique, reducing oligosaccharides are coupled to negatively charged fluorescent dyes such as 8-amino-naphthalene-1,3,6-trisulfonate, 4-amino-naphthalene sulfonate, or 7-amino-1,3-naphthalene disulfonate.[254–258]

Once a carbohydrate has been derivatized with one of these charged fluorescent tags, the carbohydrate molecule will possess an overall net negative charge and therefore will migrate in an electric field. Moreover, the fluorophore provides a high level of detection sensitivity and carbohydrate bands can be vizualized under UV (360 nm) or using a commercial imaging system, such as a charge-coupled device (CCD), to quantify the amount of oligosaccharide present in each band. This method permits separation of charged or uncharged oligosaccharides with high resolution and can detect single hydroxyl anomeric differences between mono- and oligosaccharides of sugars with otherwise identical molecular weight charge and sequence. The method can be combined with sequential hydrolysis using specific exoglycosidases in order to assess the structure of isolated glycans.[234]

The FACE method is a convenient and rapid procedure largely used in the quality control of recombinant glycoprotein glycosylation.[259,260]

4.4 Structural Characterization of Glycans

Complete structural analysis of purified glycans requires determination of: (a) the type and number of constituent monosaccharides including their ring form (D or L) and their anomeric linkages (α or β); (b) the positions of the linkages between individual sugars and their sequence;

and (c) the type, number, and position of any noncarbohydrate substituents. Several different methods are required to provide all the information. Commonly used methods combined GLC and HPLC chromatographies with physicochemical methods such as MS or NMR.

Monosaccharides commonly found in glycoproteins may be divided into neutral (Man, Gal or Fuc) hexosamines (GalNAc or GlcNAc) and acidic compounds (Neu5Ac or GlcA).

Additive heterogeneity comes from the possible substitution with aglycone residues such as sulfate, phosphate, or acetate groups. Prior to their analysis, monosaccharides have to be released from the oligosaccharide chain by acidic hydrolysis. Different methods are available for the analysis of monosaccharides depending mostly on the amount of material available. Several techniques, such as GLC or HPLC, allow both quantitative and qualitative analysis of monosaccharide mixtures. Other chromatographic or electrophoretic procedures just allow a rapid qualitative analysis of samples. Single separated monosaccharides may be further identified by physicochemical methods such as MS or NMR.

4.4.1 Release of Monosaccharides

Prior to their analysis, individual monosaccharides have to be released. The way in which individual monosaccharides are released and processed depends on the methods, which will be further used for their analysis. Different hydrolysis procedures using either chlorhydric, sulfuric, trifluoroacetic, or acetic acid may be used. It has to be kept in mind that the susceptibility to acid hydrolysis as well as the stability of the released units is different for each monosaccharide. Mild hydrolysis conditions may be employed to specifically release some sugars as fucose or sialic acids:

- Fucosyl residues are typically present on glycans in nonreducing external terminal positions; it is therefore susceptible to acid hydrolysis under mild conditions using diluted (0.05 M) HCl or TFA solutions.[261]
- Mild acid hydrolysis using acetic acid and/or enzymatic release with sialidase is recommended for sialic acid analysis.[262] Indeed, sialic acids represent a family of different compounds, differing by the presence of various substituents on the hydroxyl groups, which are rather labile and may be lost during the hydrolysis. The modifications have been shown to affect a wide spectrum of biological phenomena.[263] When a GLC approach is taken, methanolysis[264] is the method of choice because cleavage of all glycosidic linkages is very effective and less destruction of the monosaccharides is observed than during acid hydrolysis. Monosaccharides are converted to their methylglycosides. It should be mentioned that *N*-acetyl groups of the main sugars are completely cleaved, and a re-*N*-acetylation step should be introduced to reincorporate acetyl groups in hexosamines and sialic acids.

4.4.2 Gas–Liquid Chromatographic Analysis of Monosaccharides

GLC is a sensitive analytical technique for monosaccharide composition analysis, allowing detection of subnanomole amounts of carbohydrates. The method provides information on both the nature and the amount of the different monosaccharides.[262,265] The most commonly used GLC columns are fused-silica wall-coated capillary columns. Detection may be carried out by flame ionization detection (FID) or the gas chromatograph may be coupled to MS (i.e. GLC/MS). This last method provides a further refinement in identification.

Monosaccharides can also be identified by their specific fragmentation patterns.[266] Prior to their analysis, monosaccharides have to be derivatized. Trimethylsilylation of hydroxyl and carboxyl groups is the most widely used method.[267,268] If only neutral monosaccharides need to be measured, acid hydrolysis followed by reduction and peracetylation (alditol acetate derivatives) is preferred.[269,270]

4.4.3 Methylation Analysis

The use of methylation analysis in the structural determination of oligosaccharides represents the most classical method for defining both the substitution pattern of a given compound (in terms of linkage position, terminal sugars, branching points) and the ring size of the different monosaccharides. Methylation procedures differing in the nature of the basic reagent used for proton release have been described.[271–274] The steps of the methylation procedure are described in Scheme 2. The sequence is: (a) substitution of the different hydroxyl groups not engaged in the glycosidic linkages by methyl groups in alkaline medium; (b) hydrolysis of the methylated oligosaccharides; (c) substitution of the newly generated hydroxyl groups (previously engaged in the linkage) by another substituent such as acetyl groups; and (d) GLC separation of the different methylated ethers. The positions of methyl groups reflect free hydroxyl groups in the original monosaccharides of the native oligosaccharide, whereas acetyl groups give the position of hydroxyl groups initially engaged in the glycosidic linkages. Partially methylated and acetylated monosaccharides can be identified by GLC according to their retention time and in comparison with standard compounds.[275,276] Methylation analysis can be combined with GLC/MS analysis,

and the different methyl ethers identified on the basis of their specific fragmentation patterns obtained by electron ionization mass spectrometry (EIMS) or by chemical ionization mass spectrometry (CIMS).

Scheme 2 Steps in the methylation procedure.

4.4.4 Nuclear Magnetic Resonance Spectroscopy in the Study of Glycans

NMR spectroscopy provides a powerful and non-destructive method for structural study of carbohydrates. It can provide almost complete structural information on the glycan including: (a) the nature of the monosaccharides including the ring size; (b) the linkage anomericity; (c) the linkage position; and (d) the nature and degree of substitution by aglycon groups (e.g. sulfate, phosphate, acetyl). Generally a single ^{1}H-NMR analysis is sufficient to assign all the parameters of a known oligosaccharide according to the structural reporter group method developed by Vliegenthart et al.[277,278] The ^{1}H-NMR spectra may be divided into three distinct regions, the region between 6 and 4.5 ppm being the most important for establishing the number of monosaccharide units. The coupling constant values enable discrimination between the α and β anomericity. The bulk region (3.6–3.2 ppm) is generated by other protons (H-2 to H-5) and cannot generally be interpreted in a conventional one-dimensional analysis. The third region (1–3 ppm) is also very useful for structural determination because it corresponds to axial and equatorial protons of sialic acids as well as acetamido protons from hexosamines. Several bidimensional homo- or heteronuclear correlated spectroscopy procedures provide other types of information concerning the oligosaccharide sequence.[279] The more useful are: (a) the correlation spectroscopy (COSY) experiments which measure the coupling constant J between the different monosaccharides; (b) heteronuclear multiquantum coherence (HMQC) which allows clear identification of the carbon substitutions; (c) heteronuclear multiple-bond correlation (HMBC) which gives direct access to the monosaccharide sequence; and (d) rotating-frame Overhauser effect spectroscopy (ROESY), which allows identification of short-distance proton interactions. The nuclear Overhauser effect intensities may be easily translated into conformational information.

4.4.5 Mass Spectrometry Methods for Structural Analysis of Glycans

The introduction of new techniques such as MALDIMS and electrospray ionization mass spectrometry (ESIMS) has had a considerable impact on the application of MS to carbohydrate research. An MS experiment provides two types of structural information, namely the masses of the intact molecules (molecular ions) and the masses of fragment ions. For oligosaccharides, the structural information from MS is essentially limited to monosaccharide sequence and molecular weight, and only in exceptional cases can glycosidic linkage positions be obtained.

Derivatization of glycans, such as by methylation or coupling to fluorescent dyes, generally increases the signals or may provide specific fragmentation patterns necessary to determine glycosidic linkage positions.[280–283]

4.4.5.1 Fast Atom Bombardment Mass Spectrometry Although FABMS can be applied to native oligosaccharides, the derivatized compounds (permethylated or peracetylated) are preferred because the sensitivity of the analysis is significantly increased.[284–287] The most important fragmentation observed concerns the cleavage of the glycosidic linkages. In particular, fragment ions are predominantly formed by cleavage of the glycosidic bonds engaged with amino sugars, such as GlcNAc or GalNAc.[288] Even though FABMS is less sensitive than other more modern MS techniques, it remains the method of choice for the determination of the primary structure of glycans.

4.4.5.2 Matrix-assisted Laser Desorption/Ionization Mass Spectrometry The use of lasers for ionizing carbohydrates has become popular for analysis of both glycans and their glycoconjugates.[280,289,290] In this technique, samples are mixed with a UV-absorbing matrix such as 2,5-dihydroxybenzoic acid (DHB)[291] or 2′,4′,6′-trihydroxyacetophenone (THAP)[289] and are ionized within the mass spectrometer by irradiation with a UV

laser. Spectra are usually examined with a linear time-of-flight (TOF) mass spectrometer, but greatly increased resolution can be obtained with a reflectron-type mass analyzer. The MALDIMS technique can be used for analysis of large molecules such as glycopeptides or intact glycoproteins. The technique is particularly useful for determining the presence or absence of glycosylation in a glycoprotein and may be combined with deglycosylation experiments using exo- or endoglycosidases.[292–294]

4.4.5.3 Electrospray Ionization Mass Spectrometry

The major application of ESIMS is in the analysis of glycopeptides and glycoproteins which possess multiple charge sites. The method is of particular interest for glycoform study[295,296] and for determination of the glycosylation site occupancy. Glycopeptides are obtained by proteolytic digestion of the native glycoproteins, separated by HPLC and analyzed by ESIMS. A number of methods have been devised to identify the glycopeptides in such analyses using either specific endoglycosidases or specific daughter ions characteristics of the carbohydrate (e.g. m/z 204 from *N*-acetylhexosamine) to highlight the glycopeptides peaks.[296,297] The method can be coupled to microbore liquid chromatography (LC), permitting on-line LC/ESIMS analysis, or to capillary electrophoresis which is useful when complex mixtures of peptides and glycopeptides are being examined (e.g. after proteolytic digestion of a glycoprotein).[298–300] Free neutral carbohydrates lack a natural charge size and are more difficult to ionize by ESI. However, due to the propensity of carbohydrates to attract sodium, sodium salts can be added to the spray to enhance ionization.[301] Increased sensitivity can be achieved by introduction of a constituent charge, after derivatization of free oligosaccharides with UV or fluorescent dyes by the reductive amination method or other procedures.[302–305]

5 CONCLUSIONS

The study of the glycosylation pattern of glycoprotein remains an enormous task due to the extreme heterogeneity of the glycans present at each glycosylation site. Physicochemical methods such as MS analyses associated with powerful separation procedures such as HPAEC, CZE, or FACE have made structural studies feasible on very small quantities of material. Improvements to these new methods have enabled the characterization of new types of glycosylation. Structural glycobiology has become part of the ''post-genome'' program, and the study of glycosylation can no longer be considered independent of protein characterization. New strategies, such as the proteomic approach,[306,307] propose to study both glycans and peptidic sequences in a single step.

The majority of proteins are decorated with one or more covalently linked carbohydrate chains, and are thus glycoproteins. These carbohydrate chains may consist of mono-, oligo- or polysaccharides, which can affect the physiological behavior and biological functioning of the glycoprotein. Insight into the structural aspects and characteristics of glycoprotein glycosylation is an important step in unraveling the function of carbohydrate chains in a glycoprotein. In most cases the glycan and protein moieties are cleaved and analyzed separately. Nuclear magnetic resonance (NMR) spectroscopy is a powerful tool in this respect. A plethora of NMR techniques are available to obtain NMR parameters such as chemical shift, scalar coupling constants and relaxation and cross-relaxation properties. From these, both primary structural, three-dimensional structural and dynamical features can be determined for these molecules. In this article, several aspects of glycoprotein structural studies will be discussed, and a selection of NMR experiments, including experimental conditions, will be presented.

1 INTRODUCTION

Proteins are among the most important biomolecules. More than 50% of all proteins are decorated with one or more covalently linked carbohydrate chains, and are thus glycoproteins. These carbohydrate chains may consist of mono-, oligo- or polysaccharides, which can affect the physiological behavior and biological functioning of the glycoprotein. Insight into the structural aspects and characteristics of glycoproteins glycosylation is an important step in unraveling the function of carbohydrate chains in a glycoprotein.[1–3]

Until recently, the NMR analysis of intact glycoproteins was too elaborate and/or too difficult to do. Only in recent years have some glycoprotein NMR studies been presented. In most cases, the structural analysis is subdivided into smaller problems. Initially, the glycan and the protein moieties are cleaved, and analyzed separately. In some cases this is followed by a study of the intact glycoprotein. The cleavage can be achieved enzymatically or chemically. The peptide sequence has to be analyzed also, in cases where it is not yet known. The monosaccharide composition and branching information can be established through chemical means. NMR spectroscopy has proven to be a suitable tool to determine the primary sequence of the glycan in combination with the monosaccharide data. In many studies the analysis was considered complete when the primary glycan structure had been determined. The combination of modern equipment and the desire to gain a fundamental understanding of the structure–function

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

relation resulted in more advanced studies. These studies include conformational analysis and spatial structure determination of both the glycan and the protein, as well as of the intact glycoprotein. Insight into the molecular mobility and flexibility is important in order to understand complex functions and interactions, such as molecular recognition processes. Again, NMR spectroscopy is a suitable tool to obtain this information. In this article, several aspects of glycoprotein structural studies will be discussed.

2 SAMPLE PREPARATION

In order to obtain the most information from NMR spectra, the preparation of the samples is of vital importance. Obviously much attention has to be given to the choice of solvent, to solvent conditions and to sample purity. In particular, contamination by protonated molecules should be avoided as much as possible. Depending on the type of NMR equipment, various sample holders are available, ranging from conventional NMR tubes to dedicated low-concentration, low-volume sample holders.

2.1 Solvent

For ^{1}H-NMR experiments on carbohydrates, the samples are normally dissolved in deuterium oxide (D_2O or ^2H_2O), a solvent that closely resembles the natural aqueous solution, however, without the characteristic huge amount of protons. In this way, the skeleton carbohydrate protons can readily be observed. In D_2O solution all exchangeable protons (−OH and −NH) are nonobservable. Often the exchange of these protons with deuterium atoms is done in advance in one or more D_2O-dissolution/lyophilization cycles. However, in some cases one is particularly interested in these labile protons, for instance when glycopeptides or glycoproteins are studied. The amide signals are needed to obtain a complete sequential assignment of the peptide moiety. Furthermore, the observation of carbohydrate hydroxyl signals or amine and amide resonances has definite applications in the field of conformational analysis. In these cases the sample is generally dissolved in an H_2O/D_2O mixture with a D_2O content between 5% and 10%, needed for the deuterium lock system. It should be noted here that for the latter type of experiments the pH plays a crucial role. The chemical exchange of these labile protons is readily catalyzed at a pH above 7. In many cases the pH is adjusted between pH 5.5 and pH 6.5 to ensure a slow exchange. The exchange rate of hydroxyl protons is larger than that of NH-protons. The presence of metal ions (or salts in general) will have a catalytic effect on the labile proton exchange. The occurrence of paramagnetic impurities is harmful to most NMR experiments. Metal ions are conveniently removed from the sample by passing it through a small column of Calix (Bio-Rad™).

2.2 Purification and Desalting

Next to the choice of solvent, a second condition for obtaining good NMR spectra is careful sample preparation. Next to a functional fractionation of the samples using several chromatographic techniques, all proton-containing contaminating substances, such as buffer compounds, must be removed from the samples. Anionic carbohydrates and large oligosaccharides are easily desalted on small (1 cm × 20 cm) gel filtration columns (e.g. Bio-Gel™ P-2, Bio-Rad™) eluted with water. The sample is recovered in the void volume and is ready for D_2O exchange after lyophilization. If the sample contains high amounts of acetate, as can be the case after high-pH anion exchange chromatography, the use of 5 mM NH_4HCO_3 as eluent instead of pure water facilitates the removal of the acetate. Small neutral oligosaccharides can be desalted on a mixed-bed of cation (e.g. AG 50 W, Bio-Rad™) and anion (e.g. AG 1, Bio-Rad™) exchange resins. A recent advance in sample desalting techniques is the introduction of the Hi-trap column (Pharmacia).

2.3 Sample Amounts and Sensitivity

The amount of information that can be obtained by NMR spectroscopy is immense. The technique, however, is rather insensitive compared with other spectroscopic or spectrometric techniques. The first solution is to put a large amount of sample in the NMR instrument. This can be achieved by using high sample concentrations and/or using NMR tubes with a large diameter. Therefore, sensitivity is not a problem in cases where ample amounts of material are available and are soluble. However, in the analysis of released glycoprotein glycans, the total available amounts are often small (nanomolar and micromolar ranges). Using the standard NMR hardware, the best choice is to use special NMR tubes with a thick glass bottom and a glass insert (plunger) on top of the sample. These kind of NMR tubes are often referred to as ''Shigemi-tubes'' , named after the main manufacturer. The glass has a magnetic susceptibility close to that of water. Consequently, the magnetic field lines are not refracted at the sample–glass interface. The result is that the effective sample volume can be reduced from 500 to 250–300 μL. Therefore, the NMR spectra can be recorded at increased sample concentrations. To reduce the sensitivity problem further, the manufacturers of NMR instruments offer ''micro-probes'' or ''nano-probes''. In comparison with conventional NMR measurements, the

sample volumes are drastically reduced from typically 500 to 150–50 μL, respectively. In this kind of NMR probe the sensitivity gain is achieved by placing the receiver coils much closer to the (smaller) sample. Especially with the nanoprobe technology, NMR spectra of released glycoprotein glycans can be recorded with sample amounts as small as 10 nmol.

3 PRIMARY STRUCTURE

To characterize the primary structure of a glycoprotein, several structural parameters have to be determined: amino acid sequence, type of linkage of the carbohydrate chain to the polypeptide backbone, position of the glycosylation site, and the primary structure of the carbohydrate chain. The amino acid sequence can be obtained in several ways. Thus far, several different glycan–protein linkage types have been identified. *N*-glycosyl linkages between *N*-acetylglucosamine and asparagine residues, *O*-glycosylation of serine and threonine by *N*-acetylgalactosamine, *N*-acetylglucosamine, or fucose residues all occur widely. In the linkage region of proteoglycans,[4] *O*-glycosylation of serine by xylose is found. Less well known are *C*-glycosidic linkages that were discovered in recent years.[5,6] In this article the focus will be mainly on the analysis of *N*- and *O*-glycosidic linkages.

3.1 Glycan Characterization

Glycoproteins are rarely single compounds. Even when they are homogeneous in the amino acid sequence, glycoproteins may consist of a family of compounds. This is due to (micro)heterogeneity that may occur in each glycan at each glycosylation site. This feature forms a serious complication in the structure determination of the glycans. Therefore, characterization of a glycoprotein sample often starts with the cleavage of the carbohydrate chains from the intact glycoprotein along chemical or enzymatic routes. *N*-linked glycans can be split off through hydrazinolysis. Although this technique has often been applied, in general the use of enzymes has to be preferred, because fewer artifacts are introduced. Several different types of enzymes can be taken into consideration for this purpose: first the so-called endo-enzymes that cleave within the *N*,*N*-diacetylchitobiose unit. The enzymes belonging to this category have a rather strict specificity, dependent on the glycan structure. The peptide-*N*-(*N*-acetyl-β-glucosaminyl)asparagine amidase F cleaves the linkage between the first *N*-acetylglucosaminyl residue and the amide group of asparagine. Since it is an amidase, it has a very broad specificity. However, PNGase F is almost inactive when fucose is (α 1–3)linked to the first *N*-acetylglucosamine residue. In that case, PNGase A has to be preferred. Following the enzyme digestion, the cleaved oligosaccharides are purified using several chromatographic steps.

For the *O*-linked carbohydrate chains, there are no enzymes available that are widely applicable for cleavage of the whole chain. The most generally applicable cleavage reaction is based on the alkaline borohydride treatment. The resulting oligosaccharide alditols are fractionated through chromatography. Instead of splitting the carbohydrate chains from the glycoprotein, glycopeptides can be prepared through digestion of the glycoprotein with proteolytic enzymes. The structure determination of glycan fragments comprises invariably multi-step processes. A first indication of the character of the glycans with regard to molecular size and charge is obtained from the fractionation by different high-performance liquid chromatography (HPLC) techniques. The qualitative and quantitative monosaccharide composition is established after methanolysis followed by gas chromatography (GC). The absolute configuration of the monosaccharides is determined after solvolysis of the methyl glycosides with 2-butanol by GC.[7,8] The molecular masses of oligosaccharides are derived by mass spectrometric techniques such as fast atom bombardment mass spectrometry or matrix-assisted laser desorption/ionization time-of-flight mass spectrometry.

NMR spectroscopy is by far the most informative method for the determination of the glycan structures. For the primary structure, it is the only method that provides all details, comprising types of constituting monosaccharides including ring size and anomeric configuration, position of glycosidic linkages as well as type and position of non-carbohydrate substituents. Since NMR spectroscopy is a nondestructive technique, it is the most obvious first approach in the analysis of unknown glycans. Prior to NMR spectroscopic analysis, the dry samples are dissolved in D_2O and lyophilized in order to exchange the hydroxyl and amide protons for deuterium and dissolved finally in 500 μL D_2O with a high isotopic purity.

3.2 Structural Reporter Groups

The one-dimensional ^{1}H-NMR spectra of glycoprotein-derived glycans in ^2H_2O solutions show that two groups of signals can be distinguished: the so-called bulk signal and the structural reporter group signals. The former contain mainly the nonanomeric protons, present in a rather narrow spectral area, between 3.2 and 3.9 ppm. Owing to overlap this group of resonances can hardly be interpreted in terms of individual protons. The structural reporter group signals are found outside the bulk region. It appears that it is not necessary to assign all ^{1}H-NMR signals for a full characterization in terms of a carbohydrate structure.

Table 1 Structural reporter groups for glycoprotein derived glycans

- Anomeric protons
- Alkyl and acyl substituents like methyl, acetyl, glycolyl
- Sialic acid H3 atoms
- GalNAc-ol H2, H3, H4 and H5, Man-H2 and Gal-H4 atoms
- Protons shifted out of the bulk-region due to glycosylation shifts or under the influence of substituents, such as sulfate, phosphate, and acyl groups
- 6-Deoxy sugar H6 atoms

The exact location of a proton resonance in the spectrum is determined by the average magnetic field experienced by this proton. This local magnetic field depends on the primary structure (i.e. electron distribution), the spatial structure, and the mobility of the structure. The relation between the chemical shift and the structural parameters is very complex, and not easily accessible for theoretical approaches. Prominent structural reporter groups are the signals as summarized in Table 1.

The various chemical-shift patterns comprising chemical shifts and couplings are translated into structural information based on a comparison with patterns in a library of relevant reference compounds.[9–11] The comparison of NMR data for many closely related glycans resulted in empirical rules to correlate chemical shift values with carbohydrate structures. Obviously, the application of this approach requires accurate calibration of the experimental conditions like sample temperature, solvent, and pH. It is remarkable that the reporter group signals are such excellent probes of local structural elements. They are rather insensitive for alterations in the structure distant from the corresponding locus. Although the concept has proved its usefulness in the structure elucidation of numerous compounds, it should be applied with some care in the investigation of completely new structures. For definitive conclusions on the identity of novel compounds, additional experimental data from independent techniques should be collected. The application of the ^{1}H-NMR structural reporter group approach to determine the structure of *N*-glycans derived from glycoproteins was very successful.[9] A groundbreaking study was the elucidation of the structure of the glycans of α-acid glycoprotein.[12] For *O*-linked glycans of glycoproteins released as oligosaccharide alditols, we demonstrated that analogous structural reporter group signals can be identified.[9,11] Since the peripheral parts of the *N*- and *O*-linked glycans have several elements in common, the same type of structural reporter signals can be used in both cases.

The large amount of NMR data collected for quite an array of compounds enabled us to develop an NMR database for the computer-assisted identification of carbohydrates.[13] The database, designated SUGABASE, combines 1411 ^{1}H- and 590 ^{13}C-NMR chemical shifts of carbohydrate with 1756 structures and literature references as present in the complex carbohydrate structure database (CCSD).[14] The CCSD currently comprises almost 50 000 records. Starting from an input of chemical shift values, the search program produces a list of partially or completely matching structures. The SUGABASE program is available for UNIX and Microsoft Windows computers, and there is an interface to the database on the Internet at http://www.boc.chem.uu.nl/sugabase/databases.html.

The chemical shifts of these signals, together with their coupling constants, give valuable information on the structure of the glycans.[10] Also, the program is useful for the study of novel compounds, because structural elements can be traced that are occurring in other carbohydrates, already present in the database. The program can be applied for characterizing glycoconjugate-derived glycans and polysaccharides.

3.3 Protein Characterization

In many cases the amino acid sequence of the glycoprotein is known at the start of the characterization thereof. Therefore, and because it goes beyond the scope of an article on the analysis of glycoproteins by using NMR spectroscopy, this aspect of primary structure analysis will not be discussed here. The glycosylation sites, however, are not always known. Although characterization of the glycans is most conveniently done on free oligosaccharides, for the determination of glycosylation sites another approach must be followed. Instead of splitting the carbohydrate chains from the glycoprotein, glycopeptides can be prepared through digestion of the glycoprotein with proteolytic enzymes.

Depending on the specificity of the enzymes, the peptide parts can vary in length and the mixture of peptides and glycopeptides can be rather complex. Often for one glycosylation site more than one glycopeptide is found. Peptides are characterized by using N-terminus analysis in conjunction with comparison to the complete amino acid sequence. Structure analysis of the glycopeptides provides information on the identity of the glycans and on the position of the glycosylation sites in the polypeptide backbone.[15,16] The recent finding of a novel glycosylation type, C-glycosylation, complicates the analysis, because this linkage can thus far not be cleaved without destroying the entire glycoprotein.[5]

NMR spectroscopy is nowadays widely used in protein analysis. The incorporation of ^{13}C, ^{15}N and ^{2}H isotopes in proteins allows very powerful NMR experiments to be performed. Isotope labeling for glycoproteins, however,

is not frequently used as yet. The reason for this is that the common bacterial cell lines used to prepare isotope-labeled proteins do not have the glycosylation machinery that is essential to glycosylate the proteins. This means that the protein may be obtained but without most of all of its glycans, or with a different glycosylation pattern. Furthermore, the native protein folding frequently depends on the presence of glycans. Therefore one cannot be sure whether the labeled protein has adopted the same three-dimensional shape.

3.4 Glycopeptides

Glycopeptides can often be studied as intact molecules. The primary structure characterization of the glycan part is basically identical to that of free glycans. The structural reporter group method can be applied here as well. Although the chemical shifts of the monosaccharide attached to the peptide will be affected, the overall chemical shift profile will be very close to that of the free glycans. Two-dimensional NMR methods, as described in section 4 on spatial structure, can also be applied to determine the final details of the primary structure. Especially in the case of glycopeptides, this approach is very effective, because the structural reporter group approach is only applicable to the glycan moiety and the peptide moiety. Generally, the primary structures of the peptides are known from chemical amino-acid determinations. This means that NMR spectroscopy is merely used here for confirmation, and in the preparation of three-dimensional structure determinations. In most cases, however, glycopeptides are too small to have a defined spatial structure.

4 SPATIAL STRUCTURE

The properties of nuclear spins depend heavily on molecular structure and dynamics. As a consequence, NMR spectra are intrinsically rich in information on these topics. The NMR spectroscopist needs to assign the NMR resonances to individual spins in the molecule. This is a prerequisite for further analysis and extraction of valuable structural information about the molecule under study. The NMR observables used in structure analysis are primarily the nuclear Overhauser effects (NOEs) and three-bond J-coupling constants. Each NOE cross-peak corresponds with a short distance between two protons. Each three-bond coupling provides information on a dihedral angle. When the assignment of many peaks in the NMR spectra has been completed, lists of NOE cross-peaks and/or three-bond coupling constants can be obtained, providing information on interatomic distances and dihedral angles, respectively. This information can be converted into a three-dimensional model, using methods that frequently include force-field calculations.

4.1 Spectrum Assignment

Signal assignment of complex oligosaccharides can partly be done by comparing occurring chemical shifts with data stored in a library of known compounds. This technique uses the structural reporter group method. The comparison can be performed manually or with the aid of computer database programs. Though this method is valuable for characterization purposes, it does not provide sufficient signals assigned for more advanced analysis of the NMR spectra. Furthermore, the application of the structural reporter group method may fail, when a molecule with novel structural properties or with a large complex structure is studied.

Typically, homonuclear correlation type spectra, such as various correlation spectroscopy (COSY) or total correlation spectroscopy (TOCSY) experiments, are needed to assign signals in the bulk area. This kind of correlation spectrum yields spin systems that correspond to monosaccharides or amino acids (or parts thereof). The glycan assignment procedure generally starts from the anomeric proton signal, or any other well-resolved NMR signal. The two-dimensional spectra can be traversed from diagonal peak to diagonal peak via cross-peaks. In this way the resonances in each spin system can be identified.

Homonuclear correlation experiments identify spin systems. They are essential in this respect, but they do not provide sequence information. Mostly nuclear Overhauser effect spectroscopy (NOESY) or rotating frame nuclear Overhauser spectroscopy (ROESY) spectra are used for this purpose. Often the most intense NOESY peak identifies the linkage location. There are, however, several examples known where the most prominent NOESY peak represents a short distance to another proton. Care should be taken here, because NOESY interactions are through-space interactions and the shortest inter-proton distance may be a long-range interaction with respect to the primary structure. An unambiguous method to resolve this problem is the heteronuclear multiple bond coherence spectroscopy (HMBC) experiment, which yields through-bond correlations. This yields cross-peaks between the anomeric carbon and the ring proton of the adjacent sugar residue, and between the anomeric proton and the ring carbon of the adjacent sugar residue. In order to make use of HMBC spectra, the carbon resonances should be assigned as well as the proton resonances. Heteronuclear single quantum coherence spectroscopy (HSQC) or heteronuclear multiple quantum coherence spectroscopy (HMQC) spectra provide one-bond $^{1}H-^{13}C$ correlations. In other words they identify chemical bonds between ^{1}H and ^{13}C, and thus

provide the link between the assigned proton resonances and the carbon resonances. The HMBC experiment is basically a HMQC experiment tuned at small (1–10 Hz) heteronuclear couplings. Often the one-bond correlations are explicitly filtered out of the spectrum. However, in our laboratory this filter is hardly used, because omitting the filter gives many one-bond correlations that are useful in the assignment process.

4.2 From Nuclear Overhauser Effect Towards Spatial Structure

NOE cross-peak intensities depend strongly, among other parameters, upon inter-proton distances. Often the NOE cross-peak intensities are assumed to be proportional to r^{-6}, where r is the inter-proton distance of the protons to which the cross-peaks were assigned. Although this is generally incorrect, a slight modification of this approach provides a decent set of intramolecular distances which are only marginally affected by the spin-diffusion process or multiple spin relaxation effects. This method is called the ''initial rate approach''. For the initial rate approach, several NOESY experiments need to be recorded at various mixing times. The cross-peaks need to be integrated. By fitting a polynomial function to these integrals as a function of the mixing time, τ_m, the slope (initial rate) at $\tau_m = 0$ can be estimated.

The experimental NOE cross-peaks can be either negative or positive. This depends on the magnetic field (i.e. the Larmor frequency) and the molecular tumbling, expressed in the rotational-correlation time τ_c. For molecules having a τ_c near the critical value of $\sqrt{5/(2w)}$ no NOEs can be measured, and NOESY is not applicable. Small oligosaccharides fall in this category. NOE-like information, however, can also be obtained from ROESY data. Quantification of inter-proton distances from rotating-frame nuclear Overhauser effect (ROE) intensities is more complicated than from NOESY data.

For small molecules, knowledge of a few distances may be enough to build an initial molecular model, although in many cases, one could find contradicting short distances. In these cases, the molecule in solution may occur in two or more significantly different conformations (Figure 1). For larger molecules, such as (glyco)proteins, several hundreds of relevant short distances may be obtained, making it virtually impossible to build a molecular model from scratch manually. Just as with smaller molecules, conflicting short distances may occur due to different conformations, making the problem even more difficult. Several computational approaches have been developed to handle this problem, such as distance geometry and simulated annealing methods, or combinations of both. These methods yield many first approximation molecular models that may represent genuinely different conformations. These models are optimized using a short molecular mechanics or molecular dynamics run.

Figure 1 600 MHz NOESY spectrum of fully glycosylated alpha human chorionic gonadotrophin (αhCG) glycoprotein hormone in aqueous solution. The spectrum was recorded on a Bruker AMX-600 spectrometer at an elevated temperature of 333 K, with a NOE mixing time of 125 ms.

5 MOLECULAR MOBILITY

To gain insight into the function of oligosaccharides, glycoproteins, peptides or any other biomolecule, the determination of the spatial structure is a prerequisite. X-ray diffraction, NMR spectroscopy and computational methods are available to obtain molecular structures. Knowledge of the structure alone, however, is often not enough, since molecular flexibility is in most cases essential to their function in biochemical processes. NMR not only provides the tools to determine the spatial structure, but the internal molecular flexibility can also be studied. In NMR spectroscopy, molecular motions are reflected in the relaxation behavior of various NMR observables. The way in which NMR parameters, such as chemical shifts and coupling constants, and dipolar interactions, are affected depends on the relative timescale of the molecular motions. Atomic motion results in reduced NOE cross-peak intensities. The theory behind the NMR relaxation processes is well understood and can be used to determine both the molecular conformation and the molecular flexibility.

5.1 Conformation and Flexibility

Valuable NMR parameters for conformational analysis of biomolecules are the proton–proton NOEs or ROEs. They depend strongly on inter-proton distances and on the mobility of the inter-proton vectors. In the standard approach the mobility of all proton–proton vectors is considered to be constant. This is the so-called isotropic approximation. Now the cross-peak intensities are only a function of all inter-proton distances, and the ''overall'' tumbling rate (τ_c). This approximation is most useful to determine single conformational molecular models. In practice, however, various distinctly different conformations may occur. How these conformations affect the NMR spectra depends upon the timescale on which the conformations interconvert. In the very slow limit, the NMR spectrum will contain duplicate signals for the same nucleus. In this case, the spectrum is like a spectrum recorded for a mixture of molecules. A typical example of this kind of very slow interconversion is the α/β anomerization of reducing sugars in neutral, aqueous solution. At the other end of the timescale (faster than 1 ps) conformations change so rapidly that from a NMR point of view only the time-averaged structure can be observed. The rotation of a (hydroxy-)methyl group is a characteristic example of a very fast conformational change. It is the timescale region in between the extremes where most relevant conformational changes occur. NOEs and ROEs are especially sensitive for mobility in the microsecond to nanosecond timescale. In this regime the faster conformational changes happen, such as conformational changes in glycosidic linkages and glycan ring conversion. The NOESY spectra are now best analyzed, taking into account local mobility within the molecule that is faster than the overall tumbling rate. This is generally done with dedicated software, such as the CROSREL program.[17] Two application examples are given.[18,19] Conformational changes, however, occur at any timescale. Mostly, the effects can be observed by using T_1, T_2 and $T_{1\rho}$ relaxation times. For exchange rates between 1 μs and 1 ns, NMR spectroscopy does not have suitable parameters to judge the mobility. For the remaining exchange rates various NMR techniques are available.

As an example of the use of relaxation rates we would also like to mention the study on the mobilities of the glycan residues attached to Asn-78 of αhCG.[20–22] (Figure 2).

Figure 2 NMR structure of αhCG glycoprotein hormone obtained from NOESY data using the XPLOR program. Two well-defined protein regions are displayed on an atomic backbone level. The mobile protein region is represented by a ribbon. The glycan moieties are reduced to the first GlcNAc residues at Asn-52 and Asn-78, and are displayed on an all-atom level.

5.2 Interaction and Recognition

For the study of the conformation of oligosaccharides in oligosaccharide–protein complexes, transferred NOE (TRNOE) experiments[23,24] can be informative. Weakly bound ligands ($K_d \geq 10^{-6}$) in fast exchange (100–1000 Hz) between free and bound states can transfer NOEs obtained in the bound state to the free state. Since the line width of the ligand in the bound state is generally larger than that in the free state, and since the ligand must be present in excess, the signals from the free state ligand will dominate the spectrum. The NOE obtained in the bound state, however, is much stronger than that obtained in the free state. This causes the observed NOE peaks to be dominated by the conformation in the bound state. The TRNOE technique has been applied in a study of the binding of oligosaccharides to antibodies,[25,26] and to lectins.[26–28]

Laser photochemically induced dynamic nuclear polarization[29,30] is an advanced NMR technique that allows the detection in proteins and glycoproteins of surface exposed side chains of the aromatic amino acid residues tyrosine, tryptophan, and histidine. The

suitability of the method was demonstrated to study carbohydrate–protein interactions intramolecularly within glycoproteins[31] and intermolecularly for carbohydrate–lectin interactions.[32,33]

6 OVERVIEW OF NUCLEAR MAGNETIC RESONANCE EXPERIMENTS

NMR spectroscopy is renowned for its use of acronyms to identify the various available spectroscopic experiments that are mostly called pulse sequences. The large number of available pulse sequences and names obscures the fact that many multidimensional NMR experiments differ only in details. Pulse sequences can be categorized in different ways. Here we will classify them based on the magnetization transfer mechanism, which is linked to the information obtained from the resulting spectra. Two different pathways of magnetization transfer exist. All multidimensional NMR experiments use either one of these pathways, or combinations thereof.

Apart from the huge amount of experimental techniques available, NMR spectroscopy is often treated with caution because of the supposed need of quantum mechanics to understand the behavior of the nuclear spins. Fortunately, most experiments can be simplistically but effectively described in pictorial ways. For more comprehensive reviews of NMR theory, see Harris,[34] Ernst et al.,[35] Derome[36] and van der Ven,[37] and for a detailed practical overview see Braun et al.[38]

NMR experiments can be categorized based on the magnetization used or information transfer pathway. First, magnetization can be transferred through chemical bonds via the so-called scalar or *J*-coupling. This is the effect that causes the fine-splitting of NMR signals of individual nuclei. NMR spectra based on this route are often used for the assignment of NMR signals, because of the chemical relation between interacting nuclei. Second, magnetization can be transferred through space via cross-relaxation. Cross-relaxation is the effect when relaxation of the spin-state of a nucleus is stimulated by the close presence of one or more other nuclei. NMR spectra based on this route provide information on the spatial structure of the molecule.

6.1 Correlation Spectroscopy[38,39]

The COSY experiment was the first two-dimensional NMR experiment to be proposed and is still used today, although it has several drawbacks. Its strength, however, is that it provides information on proton pairs that are visibly coupled to each other in the one-dimensional NMR spectrum (fine splitting of the signal). With COSY there is no net magnetization transfer, which means that the cross-peaks have a zero integral. Half the multiplet signals are positive, whereas the other half is negative. As long as the *J*-coupling is larger than the line width this causes no problems. When the *J*-coupling becomes small compared to the line width, the cross-peak magnitude is reduced by the cancellation of the positive and negative multiplet

Figure 3 Demonstration of the signal canceling effects in simulated cross-peak cross-sections in COSY type spectra. Canceling occurs in cases where the *J*-coupling constant is smaller than the line width. A comparison is made between COSY and TOCSY peaks. In cases (a) through (d) the line width was set to 3 Hz, with varying *J*-coupling values: (a) $J = 12$ Hz; (b) $J = 6$ Hz; (c) $J = 3$ Hz; (d) $J = 1$ Hz.

signals (Figure 3). A second drawback, especially in the field of carbohydrate NMR, is the dispersive character of the diagonal peaks. Because of their long tails, the dispersive signals severely hamper the analysis of cross-peaks close to the diagonal. Preferred alternatives for COSY are double quantum filtered correlation spectroscopy (DQF-COSY) and TOCSY with a short mixing time.

6.1.1 Practical Information

Only hard 90° pulses are needed.

6.2 Double Quantum Filtered Correlation Spectroscopy[38,40]

The dispersive character of the diagonal peaks hampers the analysis of cross-peaks close to the diagonal using conventional COSY. Implementation of a double quantum filter, which allows only peaks involving two different spins, cancels the diagonal signals, including the solvent signal, to a very large extent. Now cross-peaks in the bulk area can also be analyzed. The problem of signal cancelling within the cross-peak multiplet still exists.

6.2.1 Practical Information

Only hard 90° pulses are needed.

6.3 Triple Quantum Filtered Correlation Spectroscopy[38,40]

In DQF-COSY a filtering technique is used that allows for cross-peaks between coupled protons that share at least a third proton to which they are mutually coupled. Triple quantum filtered correlation spectroscopy (TQF-COSY) is a COSY experiment with a triple quantum filter, which yields cross-peaks only when at least three spins are directly coupled. In practice this technique is often used to obtain COSY spectra containing H5/H6/H6′ cross-peaks in hexapyranosides, or H4/H5e/H5a cross-peaks for xylose, or similar triply coupled signals. This may be needed to overcome signal overlap in DQF-COSY spectra. TQF-COSY is not often used. It may, however, be useful in the case of Gal or GalNAc residues to assign the H5, H6 and H6′ atoms that cannot be found in TOCSY spectra.

6.3.1 Practical Information

Only hard 90° pulses are needed.

6.4 Total Correlation Spectroscopy[38,40,41]

In our laboratory, TOCSY, formerly also called HOHAHA (Homonuclear Hartmann Hahn spectroscopy) is the method of choice to assign as many protons as possible. TOCSY with a short mixing time, i.e. 8–16 ms, yielding spectra with approximately the same information content as DQF-COSY spectra would do, although with increased sensitivity. These experiments mostly have intense cross-peaks between the directly coupled protons. Often low-intensity cross-peaks are found, due to the relay of magnetization to the next coupling partner. This serves as an aid in the assignment. Not only the directly coupled proton is found on one track, but also those that are one or more coupling steps further. TOCSY with longer mixing times, typically up to 120 ms, may yield the complete subspectrum of one monosaccharide. The intensity of a TOCSY cross-peak depends on the magnitude of the J-coupling constants and on the mixing time. For Gal and GalNAc, where the coupling constants between H4 and H5 are small (<1.5 Hz), it is virtually impossible to obtain a full subspectrum. In these cases the magnetization transfer from the well-resolved H1 atom reaches the H4 but not the H5. H5, H6 and H6′ could be identified using TQF-COSY in combination with NOESY or ROESY experiments.

TOCSY does not suffer from the cross-peak cancellation when the line width is greater than the J-coupling (Figure 3). Occasionally the fact that TOCSY relays the magnetization over the whole spin system is a drawback. One is not always sure whether a cross-peak is a genuine 'COSY' type cross-peak or a RELAY-COSY peak. In these cases we still use a DQF-COSY experiment.

The occurrence of cross-peaks due to NOEs in the rotating frame (ROESY type cross-peaks) is a common artifact in TOCSY spectra. They can be distinguished from the intended TOCSY peaks by their invert sign. This effect is a smaller problem for free oligosaccharides than for larger molecules such as proteins or glycoproteins. The reason for this is that free oligosaccharide ROESY type cross-peaks build up slowly. For large molecules clean-TOCSY is often used, where the ROESY type relaxation is cancelled by NOESY type relaxation.

A second potential problem is the sample heating that may be caused by using intensive radiofrequency power, especially in cases when long mixing times are used. Heating can be detected by a changing lock signal level and will result in t_1 noise. In practice, a warming-up period of some 5 min suffices to overcome the effects of sample heating. At the end of this period the most critical shim(s) can be adjusted.

6.4.1 Practical Information

Mixing sequence: MLEV-17. Excitation using a hard 90° pulse and softer pulses (60, 90 and 180° pulses) to obtain a spin-lock field strength of 8–10 kHz. Effective 90° pulse: 25–30 μs. For TOCSY the effective 90° pulse corresponds to the actual 90° pulse. For clean TOCSY the length of the

clean delay should be included in the calculation. In our laboratory the clean delay is set to the same value as the length of the 90° pulse. Thus a 90° pulse of 16.66–20 μs is used. Mixing time: 8–150 ms for small molecules; 8–80 ms for (glyco-)proteins.

6.5 Heteronuclear Single Quantum Coherence Spectroscopy[38,41]

The HSQC experiment exploits the high sensitivity of protons compared to other nuclei such as ^{13}C and ^{15}N. This experiment yields a correlation spectrum for ^{1}H, ^{13}C and ^{1}H, ^{15}N, respectively, by a double insensitive nuclei enhanced by polarization transfer (INEPT) transfer step. For many years it was difficult to acquire heteronuclear correlation spectra for compounds having a natural abundance of ^{13}C isotopes. The emerging magnetic field gradient techniques have reduced these limitations dramatically. For HSQC the proton signal is detected. With a natural abundance of about 1.1% for ^{13}C, 98.9% of the protons are bound to a ^{12}C atom. This means that 98.9% of the detected signal must be eliminated. Without the use of magnetic field gradients, this could only be achieved by phase-cycling. Phase-cycling is a technique that cancels the unwanted signal by subtraction of free induction decays (FIDs) recorded with different phases of the radiofrequency pulses. Each FID, however, contains the unwanted signal for which the receiver has to be put at lower sensitivity. Furthermore, subtraction cancels the unwanted signal but not the associated noise. Using gradient techniques, the unwanted signal can be eliminated before the acquisition, resulting in a much higher sensitivity and preventing dynamical range problems. A further development in recent years is ''sensitivity enhancement'', mostly together with gradient coherence selection. To obtain narrow cross-peaks, normally the absorption mode signal is recorded and the dispersive signal is cancelled by phase cycling. Sensitivity-enhanced spectra allow both the absorption and dispersive mode signals to appear in the FID. In the processing stage these are separated, processed in such a way that an absorption mode spectrum is obtained with a sensitivity enhancement up to 1.41 ($\sqrt{2}$). The pulse sequence is longer, which allows for some relaxation and consequently loss of intensity. Typical sensitivity enhancements are about 1.3.

6.5.1 Practical Information

Hard 90 and 180° ^{1}H pulses and hard 90 and 180° ^{13}C pulses inversely detected. In order to obtain the shortest ^{13}C pulses the spectrometer is wired such that the output of the amplifier goes directly into the probehead. This wiring scheme prevents radiofrequency power loss in the pre-amplifier circuit, but at the same time prevents detection of the ^{13}C-NMR signals.

Depending on the available hardware, ^{13}C decoupling is possible during acquisition. A composite pulse decoupling scheme such as WALTZ or GARP is mostly used here.

To obtain a higher digital resolution in the indirect dimension, the carrier frequency and the sweep width in the ^{13}C domain may be adjusted, such that some signals are folded back into the spectrum in an empty region.

6.6 Heteronuclear Multiple Quantum Coherence Spectroscopy[38,41,42]

The information content of HMQC and HSQC spectra is the same. Both provide a correlation between ^{1}H and an X nucleus, mostly ^{13}C. The differences are hidden in the pulse-sequence. HSQC has more pulses and delays than HMQC and the period between the excitation pulse and the acquisition is longer in the case of HSQC. Therefore, HMQC is the preferred technique in cases where the accuracy of radiofrequency pulse lengths and radiofrequency pulse phases is not considered optimal. This may apply for the older hardware. Also, HMQC may be preferred in cases where T_2 relaxation is fast. A disadvantage of HMQC is that the cross-peak line widths are generally larger than those in the HSQC, because there is no proton decoupling in t_1.

6.6.1 Practical Information

See HSQC.

6.7 Heteronuclear Multiple Bond Coherence Spectroscopy[38,41,42]

The HMBC experiment is very important in unambiguous sequential assignment of carbohydrate residues, through the inter-glycosidic heteronuclear long-range coupling. Experimentally, the HMBC experiment is very similar to the HMQC experiment, where magnetization transfer is tuned to small heteronuclear couplings and the decoupling during acquisition is turned off. In many HMBC experiments the residual one-bond interactions are filtered out. In our laboratory this filter is purposely omitted. The presence of single bond correlations is useful for assignment purposes, because both HMBC and HMQC information are present in the same spectrum.

6.7.1 Practical Information

See HSQC.

6.8 Nuclear Overhauser Enhancement Spectroscopy[38,41,43]

NOESY spectra provide information related to inter-proton distances, and is therefore a valuable tool for structural analysis of carbohydrates, proteins and glycoproteins. The first application is determination of the primary structure of oligosaccharides and/or proteins. The linkage information cannot be found out unambiguously with NOESY and the observed NOE may be long range. This should be evaluated very carefully. HMBC provides this kind of information unambiguously, but at much lower sensitivity. The second application, by further analysis of NOESY spectra, is the determination of the (average) three-dimensional solution state structure of the molecules under study. NOEs can be used in a modeling study, either directly or by converting them into distance constraints. The sign and magnitude of the NOE do not only depend upon the inter-proton distances, but also on the overall (and local) mobility expressed in the rotational correlation time (τ_c). For large molecules (small τ_c) the NOESY cross-peaks have the same sign as the diagonal peaks, whereas for very small molecules the cross-peaks have the opposite sign. Di- and trisaccharides are generally in the area where the sign of the cross-peaks is changing, and can therefore not be analyzed with NOESY. In these cases ROESY experiments are the only alternative.

6.8.1 Practical Information

Only hard 90° proton pulses are needed. Solvent presaturation is normally done, using a low power radiofrequency pulse of 0.75 to 1.5 s. During the NOESY mixing time the solvent can be saturated as well. When the spectrometer is equipped with magnetic field gradients, a purging gradient may be given in the NOE mixing period, otherwise a homo-spoil pulse can be used.

6.9 Rotating Frame Nuclear Overhauser Enhancement Spectroscopy[38,44]

ROESY experiments yield spectra with cross-peaks of closely spaced protons. In this respect it is pretty much comparable to NOESY, although the experimental conditions differ. In contrast to NOESY, this experiment does not have a sign change depending on the size or mobility of the molecule. The cross-peaks are always negative relative to a positive diagonal. Positive cross-peaks do occur in ROESY spectra. Three possible causes for these phenomena exist. First, with chemical exchange, positive cross-peaks are obtained. Second, spin diffusion can be the cause. The first ROESY transfer inverts the sign of the cross-peak. Propagation via a second ROESY transfer within the same mixing period inverts the sign again, yielding a positive spin diffusion peak. Recording both ROESY and NOESY spectra is a method to analyze spin diffusion. Third, with ROESY being a spin-locking technique like TOCSY, it may suffer from TOCSY transfer, causing positive TOCSY peaks. TOCSY transfer may also give spurious peaks due to TOCSY transfer of cross-peak information to a third proton. Minimization of TOCSY transfer in the experimental phase is important for which several techniques are available, such as transverse ROESY (T-ROESY)[45] and off-resonance ROESY.[46] Equally important is coping with TOCSY transfer in the analysis phase. The CROSREL program[17–19] corrects for decreased ROESY cross-peak intensities caused by TOCSY transfer between the protons involved. Relay effects are not considered in this program.

6.9.1 Practical Information

Normally a hard 90° proton pulse is used for excitation. Solvent presaturation is normally done using a low-power radiofrequency pulse of 0.75 to 1.5 s. Spin-locking for conventional (not T-ROESY[45] or off-resonance ROESY[46]) is achieved at a field strength of 2–3 kHz (90° pulse corresponding to 125–90 µs). T-ROESY and off-resonance ROESY can be performed at higher field strengths, comparable to TOCSY experiments (10 kHz). For conventional ROESY the carrier frequency during spin-locking needs to be carefully chosen. This is important to reduce TOCSY artifacts on the one hand, and to obtain meaningful ROESY intensities on the other hand. The tilt angle θ of the most distant signal in the spectrum should be larger than 60°. Equation (1) shows the relation between θ, the spin-lock frequency ν_0 and the frequency of the most distant signal, ν_1:

$$\tan(\theta) = \frac{|\nu_1 - \nu_0|}{\gamma B_1} = \frac{|\nu_1 - \nu_0|}{4P_{90}} \qquad (1)$$

where P_{90} is the length of the 90° pulse at the spin-locking power in microseconds and B_1 is the magnetic field strength of the radiofrequency pulse.

Carbohydrates, including monosaccharides and sugar alcohols, are widely distributed in nature, being found in plants, animals and micro-organisms. They occur free, or in glycosidic linkage as polysaccharides or glycoconjugates (glycoproteins and glycolipids). It is important that suitable and sensitive methods are available for the analysis of these sugars, as in many cases only very small (microgram) amounts of material may be available. Polysaccharides and glycoconjugates must first be depolymerized to produce the monosaccharides quantitatively. The total carbohydrate released in these reactions may be determined by spectrophotometric or enzymic procedures.

Numerous separation and detection methods are available to measure the individual sugar components. Paper and thin-layer chromatography were two of the earliest techniques available, giving mainly qualitative values for individual sugar components. Major advances were made first in gas–liquid chromatography (GLC) and then with various types of liquid chromatography (LC) in the separation of individual sugars.

High-performance liquid chromatography (HPLC) and capillary electrophoresis (CE) are now two of the most commonly used techniques in sugar chromatography. Highly sophisticated detection systems, such as mass spectrometry (MS) for gas–liquid chromatographic separations, and spectrophotometric, fluorometric and electrochemical detection systems for LC of carbohydrates with suitable chromophores or fluorophores have been developed.

Carbohydrates have been derivatized for use either in precolumn or postcolumn chromatography, resulting in the detection limit in the most sensitive systems approaching yoctomole levels for individual sugars.

1 INTRODUCTION

1.1 Monosaccharides

Monosaccharides are classified into triose, tetrose, pentose, hexose, etc. according to the number of carbon atoms in the molecule. Thus xylose ($C_5H_{10}O_5$) is a pentose, glucose ($C_6H_{12}O_6$) is a hexose, and rhamnose ($C_6H_{12}O_5$) is a deoxyhexose.

Monosaccharides are individual monomeric carbohydrate units of polysaccharides or glycoconjugates (glycolipids or glycoproteins) and cannot be hydrolyzed to simpler compounds.

Monosaccharides are polyhydroxy aldehydes (aldoses) or polyhydroxy ketones (ketoses) and, as reducing sugars, exist virtually exclusively as cyclic hemiacetals. Hemiacetals are formed in reactions between carbonyl compounds (aldehydes or ketones) with alcohols, as illustrated in Scheme 1.

Scheme 1 Formation of a hemiacetal from an aldehyde and an alcohol.

Crystalline sugars exist in a single form, but in solution, sugars are present in both five-membered (furanose) and six-membered (pyranose) forms. These furanose and pyranose forms themselves each exist in two anomeric forms, α and β (epimeric at C-1 in the case of aldoses and at C-2 for ketoses). The epimeric forms arise because of the rapid equilibrium between themselves and the intermediate acyclic form. This is illustrated in Scheme 2 for D-glucose (Glc), for which sugar only

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

extremely small amounts of the furanose forms exist in aqueous solution. These structures can be described in the Haworth projection form. The pyranose ring is formed by reaction of the aldehyde group (carbon atom 1) with the hydroxyl group on carbon atom 5 of the same sugar molecule to form a hemiacetal. The corresponding furanose rings are formed between C-1 and the hydroxyl group on C-4.

Scheme 2 Cyclic and acyclic forms of Glc.

Proof of the structure of Glc, together with the elaboration of the configurational basis for the classification of aldose sugars, arises from the work of Emil Fischer over 100 years ago. The structures of

commonly found monosaccharides and the established trivial names, including recommended three-letter abbreviations, of these neutral aldose sugars, are shown in Scheme 3. Sugars may occur with modifications, which may include the introduction of functionalities such as carboxyl (uronic acids), phosphate (sugar phosphates) or acetamido groups, as shown in Scheme 4. The current universal nomenclature for carbohydrates has been published.[1]

1.2 Sugar Alcohols

Sugar alcohols are those compounds obtained when the aldo or keto group of a monosaccharide is reduced to the corresponding hydroxy group. Alternative names for these compounds are polyols, polyalcohols, or polyhydric alcohols. Those sugar alcohols derived from aldoses are referred to as alditols. Alditols are named by changing the

Scheme 5 Structures of commonly occurring sugar alcohols.

suffix '-ose' in the name of the corresponding aldose into '-itol'. Problems are encountered in the naming of sugar alcohols, due to the continuing use in some cases of trivial names which were given to some of these molecules when they were first isolated and characterized in the early history of natural products. In the time-honoured way, their names reflect their original source. Thus sorbitol was isolated from *Sorbus*, mannitol from manna, adonitol from *Adonis*, and perseitol from *Persea*, the avocado. In using current systematic chemistry and nomenclature, sorbitol is D-glucitol, mannitol is D-mannitol, adonitol is ribitol and dulcitol is galactitol. In examining different possible stereoisomeric configurations of various sugar alcohols, some have a plane of symmetry and as a result are meso (or internally compensated) compounds and are therefore optically inactive. These alditols are designated by the prefix *meso*-. Examples are *meso*-erythritol, *meso*-ribitol and *meso*-galactitol. However, the prefix D- or L- is given when the derivative of a meso form has become asymmetric by substitution, or in cases where there are more than four contiguous asymmetric carbon atoms present in the molecule. In Scheme 5, examples are given of commonly found sugar alcohols.

1.3 Nucleosides, Nucleotides and Nucleotide Sugars

Nucleosides are naturally occurring compounds of the glycosylamine type, derived from Rib or 2-deoxy-Rib and a pyrimidine (uracil, cytosine or thymine) or purine base (adenine or guanine); two examples are given in Scheme 6. Those nucleosides containing ribose are derived from ribonucleic acid, and those containing deoxyribose are derived from deoxyribonucleic acid. Nucleotides are phosphate esters of nucleosides, usually containing up to three phosphate groups (nucleotide mono-, di-, and triphosphates).

Scheme 6 Structures of the nucleosides uridine and guanosine, and UDP-Glucose.

Nucleotide sugars are formed in enzyme-catalyzed reactions from nucleotide triphosphates and sugar phosphates. In a typical reaction, uridine 5′-(α-D-glucopyranosyl diphosphate) (UDP-Glc) is generated from uridine triphosphate (UTP) and glucose 1-phosphate (Glc 1-P) (Equation 1):

$$\text{UTP} + \text{Glc 1-P} \longrightarrow \text{UDP-Glc} + \text{pyrophosphate} \quad (1)$$

The nucleotide sugars in turn are involved in carbohydrate biosynthetic reactions, when the monosaccharide is transferred to an acceptor molecule which may be a growing chain of a polysaccharide or a growing chain of a glycoprotein. A variety of nucleotide sugars, such as UDP-Glc, adenosine diphosphate D-glucose (ADP-Glc), guanosine diphosphate D-mannose (GDP-Man), thymidine diphosphate L-rhamnose (TDP-Rha), and cytidine diphosphate (CDP)-neuraminic acid are involved in highly specific reactions. For example, in the biosynthesis of sucrose, the glucose residue arises from UDP-Glc, transferred from fructose 6-phosphate (Fru 6-P), but in the biosynthesis of starch the glucose residue arises from ADP-Glc which is transferred to a growing linear chain of glucose residues. Examples of nucleosides, nucleotides and nucleotide sugars are given in Scheme 6.

2 OCCURRENCE

2.1 Composition

Monosaccharides are not normally found in significant amounts in the free form in either plants, animals or micro-organisms. Instead, they are found in vast abundance in the bound form as components of glycoconjugates (glycoproteins and glycolipids) and as polysaccharides. The most common building blocks for these polymers are the hexoses, hexuronic acids, and pentoses. Hirst[2] proposed that the hexose → uronic acid → pentose transformation occurs at the monosaccharide level. Subsequent incorporation of these sugars into polysaccharides was considered to take place by an unspecified mechanism. The involvement of nucleotide sugars in these transformations was first reported by Cardini et al.,[3] who proposed that a cofactor in the conversion of galactose 1-phosphate to Glc 1-P was UDP-Glc. The suggestion that compounds of the UDP-Glc type, i.e. other nucleotide sugars, could be involved in the formation of sugars and their subsequent incorporation into polysaccharides was then made by Buchanan et al.[4,5]

The polysaccharides are found widely in plant, animal and microbial sources, mainly as either storage materials which can be readily metabolized during growth of the organism (starch, seed galactomannans, glycogen) or as structural materials, such as cellulose in plants, chitin in *Crustaceae*. The classification of polysaccharides is now accepted to include examples such as proteoglycans and peptidoglycans, where polysaccharide chains are covalently linked to form sugar–amino acid linkages to proteins and peptides, respectively. Where polysaccharide chains are linked to lipid units, the molecules are referred to as lipopolysaccharides. The number of different monosaccharide residues found in these polysaccharides usually varies from one to three or four. In glycoproteins the protein backbone may contain a variable number of carbohydrate chains, each containing up to 20 sugar residues. In glycolipids, oligosaccharide units are linked to lipid moieties. Glycolipids and glycoproteins are frequently located bound in membranes of organisms, although water-soluble glycoproteins form the major components of animal sera.

The distribution of sugar alcohols covers plant, animal, and microbial sources, but those from plants have probably been studied in greater depth.[6,7] The discovery of sugar alcohols arose from the desire, over a century ago, to find sweetening agents other than honey or sugar cane. Among the earliest sugar alcohols isolated and characterized are glucitol (sorbitol), galactitol, and mannitol. In higher plants, the main site of sugar alcohol formation is the leaf where they arise as end products of photosynthesis. From the leaf, some of these products are translocated to the root, stem, fruits, and seeds.

2.2 Depolymerization

2.2.1 Acid Hydrolysis

In order to determine the composition of any polysaccharide, or glycoconjugate, it is necessary to obtain a quantitative estimation of the sugar constituents after hydrolysis of all glycosidic linkages. These polymers contain a range of sugars having a variety of glycosidic linkages, and the conditions required to achieve total depolymerization vary from one molecule to another. Glycosidic bonds differ in their susceptibility to acid hydrolysis. The rate of release of sugars is dependent on the position and anomeric configuration of the glycosidic linkage as well as on the identity of the monosaccharide. No acid hydrolysis procedure is capable of cleaving every linkage to give a quantitative yield of each monosaccharide. Some prior knowledge of the nature of the monosaccharides and the types of linkages involved help to make a choice.

For instance, the glycosidic linkages of polysaccharides containing monosaccharides in the furanose conformation and in addition keto sugars, are readily hydrolyzed under extremely mild conditions. Fructans are completely depolymerized with 0.1 M oxalic acid at 70 °C for 1 h.[8]

Neuraminic acid (sialic acid), a common monosaccharide constituent in animal glycoconjugates, is released quantitatively with 0.05 M sulfuric acid at 80 °C for 1 h, but is completed destroyed on heating in 1 M acid.[9] Successful release of neuraminic acid from serum glycoproteins has also been achieved using 0.025 M trifluoroacetic acid at 80 °C for 2 h,[10] whereas Kdo, a component of many bacterial lipopolysaccharides, is released by 1 M acetic acid at 40 °C for 6 h.[11] For most plant noncellulosic aldose-containing polysaccharides, including glucans, xylans, and galactomannans, conditions of 1 M sulfuric acid at 100 °C for 4–6 h will give complete hydrolysis with minimum loss of sugar,[12] or with 1 M trifluoroacetic acid at 120 °C for 1 h.[13] Cellulose can be hydrolyzed quantitatively, after first dispersing the polysaccharide in 72% sulfuric acid at room temperature followed by dilution to 2 M and heating at 100 °C. Carbohydrates containing uronic acid residues pose different problems, due to the greater resistance to hydrolysis of the uronosyl glycosidic bond. Incomplete hydrolysis results with the production of aldobiouronic acids and poor yields of the monosaccharide components. Improved yields are obtained by the incorporation of a prior hydrolysis step using formic acid.[14]

Amino sugars, such as *N*-acetyl derivatives, 2-acetamido-2-deoxy-Glc, and 2-acetamido-2-deoxy-Gal, are frequently found as components of glycoconjugates, especially glycoproteins containing *N*-glycan chains. During acid hydrolysis, *N*-deacetylation results, and the 2-amino-2-deoxyglycosides are resistant to hydrolysis. For complete depolymerization, treatment with 4 M hydrochloric acid at 100 °C for 6 h is necessary.[15] Minimal degradation occurs if sugars and amino sugars are released from polymeric material as methyl glycosides by heating in methanolic hydrogen chloride.[16]

2.2.2 Enzymic Hydrolysis

Hydrolysis of polysaccharides by enzymes is an attractive alternative to acid hydrolysis, because mild conditions of pH and temperature may liberate monosaccharide units in quantitative yield. Normally at least two or more enzymes are necessary to accomplish this. Knowledge of the specificity of the enzymes to be used is necessary in order to ensure complete depolymerization and the absence of any oligosaccharide material. Enzymes hydrolyzing polysaccharide material are classified into two types, the endoglycanases, which hydrolyze internal linkages and cause a rapid decrease in molecular size, and exoglycanases, whose action pattern is to release monosaccharide from the products of the endoglycanase reaction. α-Amylase is a well-characterised *endo*-α-(1 → 4)-D-glucanase which acts on starch and glycogen in a random manner to release oligosaccharides containing both α-(1 → 4)- and α-(1 → 6)-glucosyl residues.[17] Glucoamylase is an *exo*-α-(1 → 4)-D-glucosidase which acts by liberating Glc from the terminal nonreducing ends on hydrolysis of both α-(1 → 4) and α-(1 → 6) linkages.[18] In a similar way, inulin has been completely hydrolyzed to fructose and glucose on treatment with a fungal inulinase,[19] cereal β-glucans yield glucose only on treatment with a cellulase preparation,[20] and chitin can be quantitatively converted to 2-acetamido-2-deoxy-Glc with an *endo*-chitinase and *N*-acetyl-β-D-glucosaminidase.[21]

3 SPECTROPHOTOMETRIC ANALYSIS (COLORIMETRIC ASSAYS)

Many methods have been developed for the measurement of total carbohydrate in polysaccharides and glycoconjugates. These methods are usually nonspecific in relation to the measurement of individual monosaccharides, but generally will measure classes of sugars, such as pentoses, hexoses, uronic acids, deoxy sugars, and amino sugars. Frequently, the reactions are carried out in the presence of strong acid, which results in the hydrolysis of all glycosidic bonds, followed by the dehydration of the respective monosaccharides to furans, or pyrrole derivatives, which then condense with specific reagents to give colored products.[22] A number of methods useful for the measurement of total carbohydrate and alditols are listed in Table 1.[23–40] The methods are empirical and require calibration with known monosaccharides. It is important to appreciate the specificities of the methods which must be checked for interference by other classes of sugars, noncarbohydrate reducing agents, and protein. Several of the methods have proved suitable for the monitoring of carbohydrate eluates from LC columns.

3.1 Reducing Sugars

The amounts of reducing groups are frequently measured in aqueous extracts of carbohydrates, either before or after acid or enzymic hydrolysis. These assays are not specific for monosaccharides in the presence of reducing oligo or some low-molecular-weight carbohydrates. The most commonly used ones are based on modifications of the alkaline copper sulfate (Somogyi–Nelson reagent),[41] alkaline 3,5-dinitrosalicylic acid,[42] and alkaline 2,2′-bicinchoninate.[43]

3.2 Enzyme Assays

With the general availability of highly purified enzymes of known specificity, many monosaccharides and alditols can

Table 1 Chemical methods for the determination of monosaccharides and sugar alcohols

	polyols	37–40

be measured (Table 2).[44–59] The usefulness of enzymic techniques arises from the fact that, normally no prior separation from other carbohydrates is required, the reactions are carried out at pH values and temperatures unlikely to cause degradation of other products, and they convert the sugars to stoichiometric amounts of product. Most of the enzymes used in these procedures are commercially available, and those which are not may be readily isolated and purified. The experimental procedures for most of these methods have appeared in published collections.[60–62] Oxidases and dehydrogenases (oxidoreductases) are used in most of the procedures. Oxidases, which are usually highly specific, acting on only one substrate, require the presence of molecular oxygen and the monosaccharide is converted to the corresponding lactone and hydrogen peroxide. Hydrogen peroxide inhibits the forward reaction going to completion. In a coupled reaction, a second enzyme, usually peroxidase in the presence of an acceptor molecule, is used to destroy the hydrogen peroxide and produce a chromogen (Scheme 7). Whereas Glc oxidase oxidizes

ATP, adenosine triphosphate; G6-PDH, glucose 6-phosphate dehydrogenase; HK, hexokinase; PGI, phosphoglucoisomerase; PMI, phosphomannoisomerase; NADH, reduced nicotinamide adenine dinucleotide; NADPH, reduced nicotinamide adenine dinucleotide phosphate.

Glc at C-1 to produce gluconolactone, Gal oxidase oxidizes Gal at C-6 to produce a C-6 aldehyde. Dehydrogenases require the addition of a cofactor, either nicotinamide adenine dinucleotide (NAD^+) or nicotinamide adenine dinucleotide phosphate ($NADP^+$). On oxidation of the substrate, for example, Fuc by Fuc dehydrogenase, an equimolar amount of cofactor is reduced and from its absorbance at 340 nm, the amount of sugar can be directly determined (Scheme 8).

Scheme 7 The oxidation of Glc by Glc oxidase.

Scheme 8 The oxidation of Fuc by Fuc dehydrogenase.

Dehydrogenases frequently do not demonstrate absolute specificity for a substrate. Instead a number of structurally related monosaccharides may act as substrates. The enzyme Fuc dehydrogenase, purified from pig liver, acts not only on Fuc but also on Ara, L-lyxose, L-xylose, and L-Gal.[63] However, the latter sugars are not found commonly in biological extracts in the presence of Fuc. Similarly, Gal, D-Fuc and L-arabinopyranose are oxidized by Gal dehydrogenase.[44,64] When Gal and L-arabinose are present in the same sample, for instance in hydrolysates of polysaccharides such as L-arabino-D-galactans, the amount of Gal can be obtained from action of Gal oxidase, an enzyme with specificity only for Gal, and the amount of Gal plus L-arabinose can be obtained from the action of Gal dehydrogenase. Mixtures of the monosaccharides Glc, Fru and Man have been measured following the sequential addition of enzymes (Scheme 9).[49] All three monosaccharides are converted to the corresponding monosaccharide 6-phosphates by HK in the presence of ATP. G6-PDH is absolutely specific for the conversion of glucose 6-phosphate (Glc 6-P) to 6-phosphogluconate and NADPH. Sequential additions of PGI and PMI convert the corresponding Fru 6-P and mannose 6-phosphate (Man 6-P) to Glc 6-P, then to additional amounts of NADPH.

Scheme 9 The sequential enzymic determination of Glc, Fru, and Man.

4 CHROMATOGRAPHIC SEPARATION OF MONOSACCHARIDES, SUGAR ALCOHOLS, AND NUCLEOTIDE SUGARS

Much of carbohydrate analysis depends on the chromatographic separation and identification of these simple sugars, which themselves may have been isolated from polysaccharides or glycoconjugates.[65–68] From the earliest reports on the separation of sugars by paper chromatography (PC), the investigator now has the choice of a large number of techniques which, in chronological order, include thin-layer chromatography (TLC), GLC, LC, including HPLC, and electrophoretic techniques such as paper electrophoresis (PE) and CE.

The PC and TLC techniques, which are generally used as qualitative measures, are the least sensitive methods for the detection of carbohydrates, and require little outlay in equipment costs. The HPLC and CE techniques, when used with detection systems such as laser-induced fluorescence (LIF) of fluorescein derivatives, give the most sensitive detection, but require considerable outlay in capital equipment and running costs. The choice of technique to be used will depend greatly, among other things, on the number of samples routinely required for analysis and the amount of material available for the individual analyses. In the analysis of complex carbohydrates associated with glycoconjugates, 50–300 ng of a mixture of oligosaccharides containing up to six different monosaccharides may be available on release from a typical glycoprotein.[69] Currently, the most sensitive system used for the analysis of carbohydrates will use either HPLC or CE. Most carbohydrates are nonchromogenic, and this results in decreased sensitivity in ultraviolet (UV) or refractive index detection. Since the late 1980s, significant advances have been made both in separation and detection methods. This has been achieved by derivatization of the sugars to allow spectrophotometric analysis to be used in the detection systems.[70] These derivatives,

after separation, may now allow detection of sugars down to as little as 100 ymol (1×10^{-24} mol) in the case of LIF of fluorescein derivatives.[71]

4.1 Paper Chromatography and Thin-layer Chromatography

The procedures to be used for the separation of sugars by PC and TLC have been well-documented and reviewed.[60,67,72] Sample preparation is crucial, because inorganic ions, proteins and lipid materials cause interference with many of the organic solvent mixtures used in the separations. The procedures for TLC are generally superior to PC, because of faster separation times, a greater variety of supports, and increased sensitivity of detection. Microcrystalline cellulose, which has a similar capacity for resolution of sugars as does PC, is commonly used as the supporting material, although alternative systems using inorganic supports, such as silica gel, are used. Resolution, in this latter case, depends on both partition and adsorption effects. The addition of inorganic salts has been shown to improve the chromatographic behavior in many of the sugar separations on silica gel.[73–75]

For the resolution of mixtures of nucleotides and nucleotide sugars, an anion-exchange form of TLC using thin layers of poly(ethyleneimine) cellulose has been used.[76] Sugars form borate complexes, and these sugar complexes have been used in the separation of glucose, mannose and galactose-containing nucleotides of the same purine or pyrimidine base.[77]

Most of the solvent systems used in PC and TLC for the separation of monosaccharides can be used for the separation of sugar alcohols,[67] but distinction between these two groups may be difficult due to the similar R_f values, although Kremer[78] has developed a solvent system for the complete separation of the common monosaccharides and sugar alcohols by TLC, and Han and Robyt[79] have reported the separation of seven aldoses and their corresponding alditols. Alditols and some aldoses have been separated on *O*-(carboxymethyl) cellulose paper in the lanthanum, calcium and barium forms.[80] The TLC methodology lends itself readily to multiple development on chromatographic plates, and new supports have allowed the automated multiple development of high-performance thin-layer chromatography (HPTLC) analysis of sugars on hydrophilic layers.[81] A variety of monosaccharides, including pentoses, hexoses, heptuloses, deoxy-sugars, and acetamidodeoxyhexose, have been resolved on aminopropyl bonded silica plates in 70% acetonitrile.[82]

After chromatographic separation of sugars or sugar alcohols, it is customary to dip papers in reagents such as silver nitrate, anisidine–phthalate or periodate–pentane-2,4-dione.[60] Similar reagents, usually as sprays, are used for detection of these compounds on TLC plates. Some extremely sensitive detection methods have been developed. Reaction of aldoses with 4′-*N*,*N*-dimethyl-amino-4-azobenzene 1-sulfonyl hydrazine produces strongly chromophoric dabsylhydrazone derivatives which allow detection of 100 pmol of sugar.[83] Most aldoses, ketoses, uronic acids and amino sugars have been detected at levels as low as 250 pmol by fluorometric detection after treatment with a malonamide spray.[84] Amino sugars have been converted to the corresponding fluorescent dansyl derivatives before TLC separation.[85] Separated amino sugars on treatment with fluorescamine at pH 9.0 give highly fluorescent pyrrolines,[86] and nanogram amounts of sugars, sugar acids, lactones and polyols have been quantified after separation on HPTLC plates following treatment with 2,7-dichlorofluorescein.[87]

Nucleotides and nucleotide sugars do not normally require reagents for detection as they are conveniently detected after chromatography by examination of plates or papers under UV light.

4.2 Gas–Liquid Chromatography

GLC is widely used for the quantitative determination of monosaccharides, sugar alcohols and those components that have been derived by hydrolysis of polysaccharides and glycoconjugates. For polysaccharides and glycoconjugates depolymerization to the corresponding monomers is necessary prior to GLC (section 2.2). Total depolymerization frequently requires treatments with mineral acids. A major difficulty is the decomposition of the liberated monomers, if drastic conditions are necessary in order to hydrolyze the more resistant glycosidic bonds. Complete hydrolysis of polymeric carbohydrates with methanolic hydrochloric acid has been shown to give higher recoveries of both neutral sugars and uronic acids.[88]

Table 3 Derivatives used for the GLC of carbohydrates

Derivative[a]	Stationary phase	Detector[b]	Refs.
Alditol acetate		FID	89–91
TMS ethers		FTIR	92, 93
TMS oxime	SP 2250	FID	94
Trifluoroacetate		ECD	95
TMS methyl-glycoside	DB5 poly(5–95% methylsiloxane)	MS	96, 97
TMS methyloxime	SP 2100	MS	98
TFA alkyloxime	OV 225	MS	99–101
Aldononitrile acetate		MS	102–104

[a] TMS, trimethylsilyl; TFA, trifluoroacetate.
[b] FTIR, Fourier-transform infrared; FID, flame ionization detection; ECD, electron capture detection.

Simple sugars are polar and nonvolatile. Therefore, for use in monosaccharide analysis, derivatization is the necessary first step, in order to increase the volatility of the sugars. The most popular methods are the formation of alditol acetates, and trimethylsilylethers.[60,67] Trifluoroacetates and aldononitrile acetates have also been used. Some of the common derivatives of sugars used in GLC are listed in Table 3.[89–104] A single monosaccharide may produce several products on derivatization because in aqueous solution aldoses and ketoses exist in a dynamic equilibrium between the two ring (pyranose and furanose) and acyclic forms.[105] Unless the anomeric center, at C-1 for aldoses and C-2 for ketoses, is destroyed, for example by reduction to the corresponding alditols, up to four multiple peaks (two from the α- and β-pyranose forms and two from the corresponding furanose forms) may appear on the chromatograms. Although the production of multiple peaks on GLC will result in a complex chromatogram, the high efficiency provided by capillary columns usually gives satisfactory separations. Reduction of aldoses or ketoses with sodium borohydride or sodium borodeuteride eliminates the anomeric centers to produce alditols which are readily converted to stable acetates.[89,90] One of the limitations in using this system for the production of alditol acetates is that carboxyl groups, as in hexuronic acids, are not derivatized, and therefore these sugars do not produce chromatographic peaks. For polysaccharides, such as red-algal galactans, containing quantities of 3,6-anhydrogalactosyl residues, which are rapidly destroyed under harsh acidic conditions, a procedure has been developed to generate stable 3,6-anhydrogalactitol acetate, as an acid-stable 4-methylmorpholine-borane.[91,106] Several methodological changes, aimed at a simplification of the original alditol acetate derivatization method, have been reviewed.[90,107]

Other common derivatives, such as trimethylsilyl and trimethylacetyl, have simple work-up procedures, but both derivatives are unstable in the presence of moisture, making decomposition on storage a major problem. In the aldononitrile procedure, aldoses are reacted with hydroxylamine to produce the corresponding oximes. Acetylation of the aldoximes results in the dehydration of the oxime to a nitrile, and acetylation of all of the hydroxyl groups. Although the anomeric centers of the aldoses have been eliminated, thus giving simpler chromatograms, contaminating peaks arising from interaction between the hydroxylamine and acetylating reagents have been reported.[102,108] In the production of *O*-methyloxime acetates from aldoses, the original anomeric center is destroyed by the reaction with *O*-methyl hydroxylamine, but a new one is generated with the production of two products (the syn and anti isomers); this results in the production of multiple peaks on chromatograms.[109]

In addition to the GLC of simple monosaccharides and alditols, as described above, there is a major interest in the separation of partially methylated monosaccharides and their derivatives. This arises from well-established techniques for sugar linkage analysis of glycosidically-linked carbohydrates using methylation and other techniques.[16,110,111] Methylation analysis is the most commonly used procedure for linkage analysis, being based on the complete etherification of all free hydroxyl groups on carbohydrate oligomers or polymers. Those hydroxyl groups involved in inter-sugar glycosidic linkages, or which bear other constituents, are not involved in the methylation process. On subsequent hydrolysis of the carbohydrates, partially methylated aldoses are converted, after reduction and peracetylation, to a partially methylated alditol acetate (PMAA), prior to separation by GLC. In early reports, using this technique, monosaccharide derivatives were identified on the basis of their retention times, against standard PMAA derivatives.[112] With the resolving power of GLC coupled with the use of MS, it is possible to determine the positions of glycosidic attachment of monosaccharide units in a carbohydrate polymer, as well as identifying the ring form (pyranose or furanose) of each of the component sugars.[113,114] The mass spectra of these derivatives give characteristic fragmentation patterns, thus allowing identification of the original monomers and the nature of the glycosidic linkages. Under electron-impact/mass spectrometry (EI/MS), the fragmentation of PMAA is orderly, predictable, and easy to interpret.[115,116] It is not possible to distinguish stereoisomers by differences in their mass spectra while using EI/MS, but in most instances they can be distinguished by their GLC retention times.[117,118] Certain pairs of methylated sugars will yield alditols with the same substitution pattern (for example 2,3- and 3,4-*O*-methylpentose). They will be inseparable by GLC, but if the reduction at C-1 is carried out with sodium borodeuteride, the resulting MS patterns for these sugars will be distinguishable by relevant isotopic shifts in primary fragment ions.[119,120] Deuterium labeling has also been used in the identification of uronic acid residues in polymers. In order to overcome the well-known problem of the resistance to hydrolysis of glycosiduronic acids, reduction of the carboxyl group with sodium borodeuteride allows incorporation of deuterium atoms into the molecule ($-CO_2H \rightarrow -CD_2OH$) to give the corresponding labeled aldose. Those hexose derivatives formed from the uronic acid may then be identified by MS.

Chemical ionization/mass spectrometry (CI/MS) has also been used to identify PMAAs after GLC.[110–112] A number of gases, including methane, isobutane, and helium have been used in CI/MS procedures, but probably

the most popular one is ammonia.[110] In general, a superiority in sensitivity of chemical ionization (CI) detection over electron impact (EI) detection is observed. An ion-trap type of detector has been recommended for PMAA analysis.[113,116] By using micro-scale methylation analysis,[121] as little as 5–10 μg of glycoconjugate may allow complete analysis when using a multiple selected-ion monitoring system, which is reported to be about seven times more sensitive than standard GLC/MS.

4.3 Liquid Chromatography

For many years, until about 1980, LC for the analytical separation of carbohydrates was conducted on low-pressure systems, usually with an anionic resin as a support. However, advances in the design of supports, pumping systems and detection systems have resulted in a variety of new methods, including HPLC,[122–124] high-performance anion-exchange chromatography (HPAEC),[125] ligand-exchange chromatography (LEC),[126] and hydrophobic interaction chromatography (HIC).[127] The major differences achieved with these methods have been that the length of time required to separate simple monosaccharides has been reduced from several hours to several minutes. The improvements in the design of either precolumn or postcolumn derivatization of the carbohydrates with the corresponding detector systems has resulted in the original detection limits of nanomoles of monosaccharides being decreased to femtomoles or even lower. A general strategy for the chromatographic separation and monosaccharide composition of polysaccharides and glycoconjugates may include LEC and HPAEC in combination with pulsed amperometric detection (PAD), refractive index, or UV monitoring.[128] The identification of monosaccharides can be achieved on-line by coupling liquid chromatography/mass spectrometry (LC/MS).

4.3.1 Anion-exchange Chromatography

Using low-pressure systems, separations of monosaccharides as their borate complexes were achieved by Khym and Zyll,[129] and modifications to the system, involving fully automatic analysis of neutral monosaccharides and oligosaccharides on quaternary ammonium ion-exchange resins have been reported.[130,131] Hough et al. used a borate–chloride gradient to separate monosaccharides[132] and polyols.[133] As uronic acids are already charged, they can be separated on anion-exchange resins, in the absence of borate ions.[134] A wide variety of aldoses, ketoses, alditols, cyclitols and oligosaccharides have been measured in the effluents from borate anion-exchange columns after periodate oxidation.[135] Mixtures of monosaccharides and alditols have been successfully separated on anion-exchange resins in the molybdate form,[136] and postcolumn detection using cysteine–H_2SO_4 and periodate oxidation detected reducing sugars and alditols, respectively.

By far the most common method currently used for the analytical separation of monosaccharides, alditols and nucleotide sugars is HPAEC. This became possible with the development of quaternary-ammonium-bonded pellicular resins stable to operating conditions of high pH. The spherical pellicular resins contribute to the high resolution of the technique by locating all of the ionic groups on the surface, which results in low diffusion. Carbohydrates, in the form of polyhydric molecules, behave as weak acids, having pK_a values of 12–14.[137] Thus in basic solutions all monosaccharides, and even oligosaccharides, are negatively charged oxy anions. With increasing hydroxide concentration, several of the hydroxyl groups become ionized, with the C-2 being the most acidic. As the mutarotation of sugars is very rapid at high pH, individual anomeric forms of monosaccharides are no longer resolved. The resulting oxy anions can be chromatographed as anions, without prederivatization, with each monosaccharide yielding a single peak. The elution order of monosaccharides correlates with their pK_a values, and excellent separations have been obtained for neutral, amino-, and acidic monosaccharides derived from hydrolysis of many glycoconjugates,[138–141] as well as for the determination of polyols in food products.[142,143] Detection of the eluted sugars may be made by PAD, where sensitivities in the low picomole range can be achieved without derivatization. In this system, the carbohydrates are oxidized at the surface of a gold electrode. The resulting gold oxide layer is converted back to native gold on reversing the voltage on the electrode, and the potential is cycled back to the analytical voltage. The method is rapid and highly sensitive, with less than 1 nmol required for a typical monosaccharide separation.[144] Amino acids and peptides arising from the hydrolysis of glycoproteins can cause fouling at the working electrode surface.[145] A guard column and a newly developed separator have been designed to eliminate most of this interference.

Alternative electrodes, based on nickel–copper, nickel–chromium,[146] and silver,[147] have been developed for the detection of monosaccharides and sugar alcohols following HPAEC. The separation and PAD of carbohydrates and alditols are improved by the addition to the alkaline mobile phase of barium and strontium ions.[148] Peak symmetry and column efficiency are improved and significant enhancement of the response of the analytes in PAD at the gold working electrode are observed. These findings have been explained in terms of a rapid formation of adducts between polyhydroxy compounds and these divalent nonelectroactive

cations.[149] Aldoses and alditols, in their borate form, may also be separated on HPLC anion-exchange resins, although retention times tend to be long.[40] Detection is usually achieved by postcolumn derivatization.

4.3.2 Ligand-exchange Chromatography

LEC on microparticulate cation-exchange resins in metal ion forms has been applied to the separation of carbohydrates. Although mainly applicable for the separation of oligosaccharides, the technique will allow separations of monosaccharides and alditols.[123,124,150] The ability of neutral sugars to form complexes with metal ions coordinated to cation-exchange resins was demonstrated by Jones et al.[151] For LEC, the metal ions (usually Ca^{2+}, Ag^{2+}, or Pb^{2+}) are electrostatically immobilized on a strong cation exchanger. Water molecules bind to the metal ion, in relation to its coordination number and, when a mixture of carbohydrates is introduced into the mobile phase, they will displace some of the bound water molecules, forming a donor–acceptor complex.[152] Parameters such as carbohydrate structure, choice of metal ion, temperature, and additives to the mobile phase will affect the stability constants of carbohydrates and thus separation. Separations of pentoses, hexoses and their corresponding alditols have been reported in a study using seven different cations.[153] Good resolution of alditols had originally been achieved on cation-exchange resins in the Ba,[154] Ca,[155] and Li[156] forms. In a detailed study on the chromatography of 14 different alditols, effective separations were obtained with cation-exchange resin in its La form, using water as the eluant.[157] On sulfonated polystyrene residues in the europium(III) form with sodium hydroxide as the mobile phase, monosaccharides and alditols have longer retention times than oligosaccharides, whereas monosaccharides and alditols are selectively retained by the resin in the iron(III) form.[158]

4.3.3 Reversed-phase Liquid Chromatography

Reversed-phase liquid chromatography (RPLC) has been applied successfully to both small and large carbohydrate molecules. In this type of chromatography, nonpolar moieties of the solute and the stationary phase undergo noncovalent association in hydro-organic media. The stationary phase is a highly nonpolar surface of a solid support having covalently bound alkyl or aryl chains at the surface. Retention of carbohydrate species requires an interaction between two nonpolar groups, the nonpolar ligand bound to the surface of the solid support of the column, and the hydrophobic moiety of the solute. Basic theoretical concepts of RPLC have been the subject of several reviews.[127,159] Nonpolar stationary phases are used, usually consisting of microparticulate silica supports with covalently bound alkyl or aryl functional groups at the surface. The most widely used stationary phases include octadecyl (C_{18})-, octyl (C_8)-, and butyl (C_4)-coated sorbents. Underivatized carbohydrates are usually chromatographed using water as the mobile phase, but in general, monosaccharides which elute first are not resolved from one another.[160] Precolumn derivatization schemes have been widely exploited for the RPLC analysis of carbohydrates. The choice of type of derivative is usually made to introduce a chromophoric group onto the saccharides to aid detection of the separated molecules. Many of the chromophores are themselves hydrophobic and the conjugates are then readily separated by RPLC. Several reviews on precolumn derivatization have been published.[70,127] Chromophoric groups are covalently attached either to the carbonyl function of the monosaccharide or, less frequently, to hydroxyl or amino groups. In modifications involving the carbonyl groups, coupling is usually with amines to form imines (Schiff bases) or their more stable products by reductive amination using sodium cyanoborohydride to give substituted amines (Scheme 10). The derivatization reactions that have been developed are well-defined, quantitative, and nondestructive (when used on oligosaccharides). Excess reagents and byproducts produced during the reactions have to be removed prior to chromatography, and the introduced chemical groups must be stable.

Scheme 10 Derivatization of aldoses by reductive amination.

The analysis of carbohydrates is hampered by the lack of chromophoric or fluorophoric functional groups. Many high-resolution separative techniques, such as HPLC, CE, and fluorophore-assisted carbohydrate electrophoresis (FACE), are not feasible without pre- or postcolumn derivatization of the carbohydrate. Introduction of a simple chromophore or fluorophore as a label at the reducing end, using the reductive amination technique, allows quantitation on a molar basis. The structures of a variety of primary amines and other selected molecules used for these applications are shown in Scheme 11.

Scheme 11 Structures of molecules used for the introduction of chromophores and fluorophores into monosaccharides. AMAC, 2-aminoacridone; ABEE, aminobenzoic acid ethyl ester; ANTS, 8-aminonaphthalene-1,3,6-trisulfonic acid; 2-AP, 2-aminopyridine; CBQCA, 3-(4-carboxybenzoyl)-2-quinolone carboxaldehyde; TRSE, 5-carboxymethylrhodamine succinimidyl ester; PITC, phenyl isothiocyanate; PMP, 1-phenyl-3-methyl-5-pyrazolone.

Table 4 Precolumn derivatization and detection of carbohydrates

Carbohydrate detected	Reagent	Wavelength (nm)	Sensitivity	Refs.
Photometric detection				
Aldoses, amino sugars	2-AP	240		161, 162
Aldoses	PMP	245		163
Aldoses	1-(4′-methoxyphenyl)-3-methyl-5-pyrazolone (PMPMP)	249		164
Aldoses	ABEE	254	10–200 nmol	165
Aldoses	9-fluorenylmethylcarbonyl (FMOC) hydrazide	263	1–3 pmol	166
Aldoses	4′-*N*,*N*′-dimethylamino-4-azobenzene-1-sulfonyl hydrazine	460	10 pmol	167
Alditols	*per-O*-benzoyl	231	10 pmol	168
Amino sugars, amino sugar alcohols	*o*-phthaldehyde	254		169
Alditols, amino sugar alcohols	2-naphthoylimidazole	234		170
Fluorimetric detection				
Aldoses, amino sugars	2-aminobenzoic acid	230/425[a]	0.1 pmol	171
Aldoses, amino sugars	2-AP	320/400[a]	0.01–10 nmol	162
Aldoses, amino sugars	9-fluorenylmethylcarbonyl (FMOC) hydrazide	270/320[a]	0.05–0.4 pmol	166
Neuraminic acids, α-keto acids	1,2-diamino-4,5-methylenedioxybenzene	373/448[a]		172
Neuraminic acids, α-keto acids	*o*-phenylenediamine	232/420[a]	<2 pmol	173
Glycamines, amino sugars, amino sugar alcohols	PITC	340/450[a]	1 pmol	174
Alditols, amino sugar alcohols	2-naphthoylimidazole	234/374[a]		170

[a] Excitation/emission wavelengths shown.

4.3.3.1 Precolumn Derivatization Sensitive detection and high resolution of monosaccharides can be obtained by a judicious choice of derivatization to introduce stable chemical groups. Strict chemical techniques are required for the fulfilment of reaction conditions. The derivatization reaction should be quantitative and excess reagents and byproducts, formed during the reactions must be easily removed. Precolumn derivatizations by reductive amination are widely used in HPLC and CE for the separation of sugars. A selection of some of the more popular derivatives and their methods of detection is given in Table 4.[161–174]

In a two-step reaction (Scheme 12) an intermediate glycamine or 1-amino-1-deoxyalditol is first formed, on interaction of the reducing monosaccharide with the ammonium ion and sodium cyanoborohydride. The glycamine is subsequently derivatized with, for example, PITC to produce a phenylthiocarbamyl derivative,[174] or with *o*-phthalaldehyde.[169]

4.3.4 Ion-pair Reversed-phase Liquid Chromatography

Ion-pair RPLC has been widely used for the separation of a number of acidic oligosaccharides but, under suitable conditions, the technique may be applied to the separation of simple sugars, sugar acids and amino sugars. Carbohydrates that are weakly acidic and exist as anions in strongly alkaline mobile phases can be separated as ion pairs on addition of hydrophobic quaternary ammonium counter-ions to the mobile phases and using polymeric stationary phases.[175] Nucleotides and nucleotide sugars have also been separated using this technique.[176] Tetrabutylammonium hydrogen sulfate, which is very hydrophobic, was used as a counter-ion. The method allows the direct separation and detection of the 4′-epimeric-uridine 5′-diphosphate sugars (UDP-Gal and UDP-Glc) down to 40 pmol.

Scheme 12 Derivatization of aldoses in a two-step reaction via the glycamine (1-amino-1-deoxy) derivative.

4.3.5 Hydrophilic Liquid-interaction Chromatography

Chromatography, involving the use of a polar stationary phase with a less polar mobile phase was originally termed normal-phase partition chromatography. Alpert[177] has proposed the term hydrophilic interaction chromatography (HILIC), when applied to chromatography driven by polar forces. This then differentiates normal-phase partition chromatography from reversed-phase (hydrophobic) chromatography. Recent progress in HILIC has been published.[178] The stationary phases commonly used in HILIC are of the microparticulate and macroporous silica type, having average particle diameters of 3–5 μm, and also sorbents in which polar phases are chemically bonded to silica gel. A few synthetic polymer supports containing chemically bonded polar phases are also available. Some examples of these stationary phases and the types of sugars capable of separation on them are given in Table 5.[170,179–183]

Detection systems used in earlier work on HILIC involved the use of refractive index detectors, which were relatively insensitive and their sensitivity to changes in solvent composition, in the case of gradient elution with organic solvents, limited their use.

Although in the case of isocratic elution the detection limit is below 25 ng for sugars,[123] evaporative light-scattering detectors give superior sensitivity.[179,180] Precolumn derivatization to introduce chromophoric or fluorescent groups into monosaccharides or alditols (Table 4) is now widely used to increase the sensitivity of detection. Some postcolumn derivatization methods suitable for HILIC are described in the following section.

4.3.5.1 Postcolumn Derivatization Methods In LC, post-column derivatization plays an important role in the automation of carbohydrate analysis. The mobile phase is constantly eluted from the solid-phase column, on which the separation is achieved. By continuously mixing a flow of reagent solution into this eluant, followed by reaction

Table 5 Silica, silica-based and polymer-based packings used in HILIC of monosaccharides

Packing	Sugars separated	Ref.
Silica gel	aldoses, alditols	179
Silica gel	alditol *per*naphthoates	170
Diol-modified silica	aldoses, alditols	180
Aminopropyl silica	aldoses, alditols	180
Amine-bonded vinyl alcohol copolymer	monosaccharides, oligosaccharides derivatized with ABEE	181
Cyclodextrin-bonded silica	aldoses, alditols	182
Vinylpyridinium polymer	aldoses	183

for an appropriate length of time, and at an appropriate temperature, the separated components of the sample are converted to derivatives that are successively monitored at a detector.

Some of the earliest methods to be used in the post-column detection of carbohydrates include those methods in which carbohydrates including mono-, oligo-, and polysaccharides, are converted to furfurals in the presence of strong acids, which are condensed with chromogenic reagents, such as phenol, orcinol, cysteine, anthrone, resorcinol, and carbazole. Those methods listed in Table 1 that were originally designed for manual operations in detecting carbohydrates,[23–32] have been modified for automatic analyzers.[184] The major drawback in the use of such reagents is that they require the use of corrosive strong acids.

In order to eliminate methods requiring the use of corrosive acids, a large number of photometric, fluorimetric and electrochemical methods have been developed for postcolumn detection of monosaccharides and alditols following LC.[184] A wide range of reagents and methods, some of which are listed in Table 6,[40,185–194] are now available for the detection of sugars. A well-recognized property of reducing sugars is their ability to reduce solutions of salts of copper(II) to copper(I).[41] Addition of chelating agents such as 2,2′-bicinchoninate or bis(phenanthroline) form chelates with the copper(I) ion, which in the former case can be measured photometrically[185] and in the latter case electrochemically.[186]

Alditols cannot be detected with these reagents because they possess no reducing properties. The usual procedure for the detection of alditols involves periodate oxidation

Scheme 13 (a) Periodate oxidation and (b) pentane-2,4-dione reaction for the detection of polyols.

of the samples to release formaldehyde, followed by the Hantzsch reaction to produce pyridine derivatives for photometric or fluorimetric detection. The two-step reaction involves, first the quantitative liberation of formaldehyde on periodate oxidation of the $-CHOH-CH_2OH$ or $-CO-CH_2OH$ groups (Scheme 13a) followed by the condensation of the formaldehyde with pentane-2,4-dione and ammonia to give the pyridine derivative (Scheme 13b). Detection is achieved by monitoring the absorption of the substituted pyridine.[40] The method is ideally suited for the determination of alditols separated in the anion-exchange mode as borate complexes. Fluorimetric monitoring gives a sensitivity of 0.5 nmol of alditol. As the initial oxidation step with periodate is carried out at high pH, aldoses or ketoses will also

Table 6 Postcolumn derivatization and detection of carbohydrates

Carbohydrate detected	Reagent	Wavelength (nm)	Sensitivity (nmol)	Ref.
Photometric detection				
Aldoses	Cu^{2+}-2,2′-bicinchoninate	562	0.1	185
Aldoses	anisyltetrazolium chloride	520	0.1	186
Aldoses	Purpald	550	100	187

release formaldehyde, but only 1 mol per mole instead of 2 mol per mole for alditols. In one of the earliest reports on the use of fluorogenic reagents being used in the detection of reducing sugars, solutions of carbohydrates heated with 1,2-diaminoethane (ethylenediamine) produced a strong fluorescence at 470 nm, with an excitation maximum at 390 nm. This has been developed as a selective fluorimetric method for the determination of mono- and oligosaccharides[190] and uronic acids.[191] Increased sensitivity, down to 1 pmol of monosaccharide, could be achieved when the reaction products were electrochemically oxidized on a glassy carbon electrode.[194] 2-Cyanoacetamide has proved to be a very versatile fluorogenic molecule, because aldoses heated in weakly alkaline solutions with this reagent produce an intense fluorescence at 380 nm.[192] The reaction products also absorb strongly at 280 nm, and can also be detected by electrolysis at a glass carbon electrode, thus allowing any one of three detection methods to be used. The reaction conditions for the photometric and fluorimetric detection differ and have been optimized separately. For separations on HPLC columns with acetonitrile as eluant, only UV monitoring is possible with this derivative.

Reducing sugars when heated with strong alkali and aromatic acid hydrazides produce yellow colors, which have been used as the basis of detection systems. The reagent Purpald, which was originally developed as a spray for the detection of reducing sugars on TLC plates, can be used for the postcolumn detection of aldoses.[187] The reaction is carried out in the presence of sodium hydroxide and hydrogen peroxide to produce a tetrazine–triazole fused ring condensate (Scheme 14).

Scheme 14 Reaction of Purpald with an aldose.

Amino sugars are present in the total acid hydrolysates of most glycoproteins and proteoglycans. These sugars exist in macromolecules such as *N*-acetyl hexosamines, but the *N*-acetyl group is hydrolyzed under the acid conditions. The amino sugars can be chromatographed and detected in addition to the amino acids, on conventional amino acid analyzers with ninhydrin reagents. The same reagent may be used for the determination of monosaccharides which have been converted to glycamines (Scheme 12) prior to ion-exchange chromatography.[189]

4.4 Electrophoresis

4.4.1 Capillary Electrophoresis

CE, which had earlier been shown to give fast, automated and highly efficient separations of peptides, proteins and nucleic acids, has been developed into a technique for the analysis of mono- and oligosaccharides and glycoproteins. The CE method now provides a powerful alternative to HPLC for the detection of carbohydrates. Its popularity is reflected in the number of recent review articles dealing with current methods and general principles.[195–199] Carbohydrates are separated in CE, under the influence of an applied electric field (5–30 kV), by migrating in capillary columns (0.5–1.5 m long, 50–100 μm internal diameter), which span two buffer reservoirs and which are filled with buffer solutions. Total capillary volumes can be 10 μL, and injection volumes can be in the range of a few nanoliters. Factors influencing the mobility of carbohydrates include the applied voltage, the charge on the sugar molecule (positive, negative, or neutral), the pH and ionic strength of the buffer, the presence of buffer additives (surfactants, ion-pairing agents), and the operating temperature inside the capillary, as well as its length and diameter.[200] Capillary columns are generally constructed from fused silica and carry negative charges on the inner surface due to the presence of silanol groups, which are ionized above pH 3.0. Two forces – electro-osmotic flow and electrophoresis – govern the mobility of the carbohydrates. The electro-osmotic flow drives all species, irrespective of charge, from the injector, through the capillary, to the detector. This flow results from the cations in the buffer being attracted to the negatively charged silanol groups on the surface of the capillary. Under an applied high voltage, the cations migrate from the anode to the cathode, resulting in a bulk flow of electrolytes (electro-osmotic flow). The electrophoretic force, which also influences the separation of the species, is considered to be weaker.

The separation of both neutral and charged sugars may be achieved by either of two modes. The most common mode uses normal polarity (positive polarity) in which a neutral or basic buffer is used, sample application is at the anode, and detection is at the cathode. Therefore sugars bearing a positive charge will elute first, followed by neutral sugars. Negatively charged sugars are retarded because of electro-osmotic flow. In the second system, reversed polarity (negative polarity) acidic buffers are used. Electro-osmotic flow is reduced or eliminated, because of loss of charge on the silanol groups. Electrophoresis is then the dominant force, and only the anionic species migrate towards the anode. Electro-osmotic flow may also be eliminated by coating the capillaries with poly(vinyl alcohol). As only a relatively small number of monosaccharides (amino sugars, uronic

acids, sugar phosphates)[201] contain either anionic or cationic functional groups, separate methods have to be used to ensure electromigration of neutral monosaccharides. These methods include ionization of hydroxyl groups at high pH, complexation of vicinal or alternative hydroxyl groups with borate or alkaline earth metal ions, derivatization with reagents containing ionizable functions and partitioning into micelles in a pseudo-stationary phase (micellar electrokinetic chromatography). Similarly to HPLC, the detection of separated carbohydrates may use refractive index detectors. As most carbohydrates lack chromophoric or fluorophoric functions, precolumn derivatization is necessary to introduce these functions in order to achieve the greatest level of sensitivity. Depending on the choice of reagent, the derivatives may themselves be charged.

Nonderivatized monosaccharides can be monitored by direct UV detection after CE, following on-column complexation with borate at high pH, although the sensitivity is relatively low.[202] Indirect detection methods, which are available for nonchromophoric sugars, are based on the displacement of the chromophore in the background electrolyte by the analyte molecule, resulting in negative peaks. Indirect UV detection using sorbate as the background electrolyte is frequently used.[203] Of a number of other background electrolytes examined, 1-naphthyl acetic acid has been shown to be a suitable carrier buffer at pH 12, for detection of sugars at 222 nm, giving both an increased separation efficiency and improvement in detection limit, compared to sorbate.[204] Tryptophan and *N*-benzyl cinchonidium chloride have also been used successfully as background chromophores.[205] The PAD of nonderivatized sugars has been developed for CE.[206]

Carbohydrates are readily detectable after precolumn derivatization, giving products suitable for UV and fluorescence detection. This is the preferred approach for the electrophoresis and detection of monosaccharides. General methods to achieve derivatization include reductive amination,[207] condensation of carboxylic groups on saccharides with amines,[208] or condensation with PMP.[209] The chemistries involved are shown in Schemes 10, 15 and 16.

The use of 2-AP as a label for monosaccharides, after reductive amination, was originally developed for the precolumn labeling of monosaccharides for HPLC (Table 4). From these *N*-2-pyridyl-glycamines derivatives, monosaccharides give a rapid separation in borate buffer at pH 10.5.[207] 2-AP reacts satisfactorily with aldoses, alduronic acids, and *N*-acetamido-hexoses, but not with ketoses. An alternative number of carbohydrate labels based on aminobenzene, including 4-aminobenzoic acid,[210] ethyl 4-aminobenzoate,[211] and 4-aminobenzonitrile[212] give derivatives with ketoses. On-column detection of 6-aminoquinoline derivatives at 245 nm, using borate based electrolytes, has been used to give very sensitive detection of monosaccharides in wood-derived hemicelluloses.[213] The minimal detectable amount is reported to be a few femtomol with concentration limits of detection of the order of 10^{-6} M.

Other commonly used derivatives for precolumn labeling of monosaccharides, using reductive amination chemistry, include ANTS and 8-aminopyrene-1,3,6-trisulfonic acid (APTS). Two major advantages shown by these derivatives are that, as they exhibit very high extinction coefficients in the UV range, they can be detected photometrically at very low levels by LIF, and that the negative

Scheme 15 Derivatization of uronic acids with carbodiimide coupling to amino compounds.

Scheme 16 Conversion of reducing sugars to PMP derivatives.

charges on the sulfonic acid groups are so strong that they are dissociated even in acidic media. In the analysis of the monosaccharide composition of glycoproteins, APTS has been used to derivatize the monosaccharide components. Neuraminic acid was separately derivatized with 9-aminoacridone.[214]

Isoindole derivatives of monosaccharides that give very sensitive labels are obtained from a two-step derivatization process. In the first step, sugars are converted to the corresponding glycamines by reductive amination (Scheme 17) prior to condensation with CBQCA in the presence of the cyanide ion.[215] The highly fluorescent isoindole derivatives of monosaccharides can be determined at attomole (10^{-18} mol) levels by LIF. The advantages and disadvantages of fluorescence and LIF have been examined in detail.[216]

In another two-step derivatization method for monosaccharides, neutral sugars are converted to glycamines by reductive amination (Scheme 12). Amino sugars are reduced to the corresponding 2-amino-2-deoxyalditols. These aminated sugars are then labeled with TRSE (Scheme 18). Difficulties have been reported with the stability of these derivatives, but, nevertheless, successful separations of hexoses derived from mammalian glycoproteins have been achieved with a concentration detection limit of 5×10^{-11} M.[217]

The formation of amide bonds from the condensation of carboxyl groups and amino groups in the presence of carbodiimide is a well-documented chemical process. Amide bond formation between alduronic acid residues and amines, such as 4-aminobenzene sulfonic acid (sulfanilic acid), and 7-aminonaphthalene-1,3-disulfonic acid (ANDSA) have been used to produce labeled carbohydrates (Scheme 15). The labeled products are strongly anionic at low or high pH levels. UV detection at 247 nm results in mass detection limits of 30 fmol for sulfanilic acid and 15 fmol for the ANDSA derivatives.[208] Under mildly basic conditions, PMP reacts with aldoses to form bis-PMP derivatives (Scheme 16). These derivatives, originally developed for HPLC, are used in capillary electrophoretic separations of mono- and oligosaccharides.[209]

4.4.2 *Fluorophore-assisted Carbohydrate Electrophoresis*

The FACE method is based, first, on the attachment of fluorescent tags to the reducing end of carbohydrates using standard reductive amination techniques prior to the separation of the derivatives on polyacrylamide (PA) gel slabs.[218–220] This technique has been used mainly for routine oligosaccharide profiling and sequencing of a variety of carbohydrates, as well as for monosaccharide analysis. The fluorophore most often used is ANTS.[221] Neutral and acidic monosaccharide derivatives exhibit net negative changes, imparted from the three sulfonic acid groups, and can be separated by electrophoresis and detected by their fluorescence. The alternative fluorophore, AMAC, which confers no charge on monosaccharide derivatives, is also used. In this case, borate ions, which complex with vicinal hydroxyl groups of monosaccharides, impart a negative

Scheme 17 Conversion of aldoses to isoindole derivatives.

Scheme 18 Conversion of glycamines into TRSE derivatives.

charge for electrophoresis.[202] These derivatives are analyzed by polyacrylamide gel electrophoresis (PAGE). High-resolution separations are achieved by virtue of the electrophoretic buffer systems used. These are so-called stacking systems that are also called discontinuous, moving boundary, multizone, or multiphase. The PA gel inhibits convection. The resultant electrofluorograms are viewed on a graphics display unit after imaging with a suitable electronics camera.

Some ANTS–fluorophore derivatives of monosaccharides, oligosaccharides and low-molecular-weight polysaccharides have been separated by PAGE. For monosaccharides, high-resolution separations of some pairs of isomers, anomers and epimers have been achieved.

ABBREVIATIONS AND ACRONYMS

ABEE	Aminobenzoic Acid Ethyl Ester
ADP-Glc	Adenosine Diphosphate D-glucose
AMAC	2-Aminoacridone
ANDSA	7-Aminonaphthalene-1,3-disulfonic Acid
ANTS	8-Aminonaphthalene-1,3,6-trisulfonic Acid
APTS	8-Aminopyrene-1,3,6-trisulfonic Acid
Ara	D-Arabinose
ATP	Adenosine Triphosphate
CBQCA	3-(4-Carboxybenzoyl)-2-quinolone Carboxaldehyde
CDP	Cytidine Diphosphate
CE	Capillary Electrophoresis
CI	Chemical Ionization
CI/MS	Chemical Ionization/Mass Spectrometry
ECD	Electron Capture Detection
EI	Electron Impact
EI/MS	Electron-impact/Mass Spectrometry
FACE	Fluorophore-assisted Carbohydrate Electrophoresis
FID	Flame Ionization Detection
Fru	D-Fructose
Fru 6-P	Fructose 6-Phosphate
FTIR	Fourier-transform Infrared
Fuc	L-Fucose
Gal	D-Galactose
GalA	D-Galacturonic Acid
GalNAc	*N*-Acetylgalactosamine
GDP-Man	Guanosine Diphosphate D-Mannose
Glc	D-Glucose
GLC	Gas–Liquid Chromatography
GlcA	D-Glucuronic Acid
GlcNAc	*N*-Acetylglucosamine
Glc 1-P	Glucose 1-Phosphate
Glc 6-P	Glucose 6-Phosphate
GulA	L-Guluronic Acid
G6-PDH	Glucose 6-Phosphate Dehydrogenase
HIC	Hydrophobic Interaction Chromatography
HILIC	Hydrophilic Interaction Chromatography
HK	Hexokinase
HPAEC	High-performance Anion-exchange Chromatography
HPLC	High-performance Liquid Chromatography
HPTLC	High-performance Thin-layer Chromatography
IdA	L-Iduronic Acid
Kdo	3-Deoxy-D-*manno*-oct-2-ulosonic Acid
LC	Liquid Chromatography
LC/MS	Liquid Chromatography/Mass Spectrometry
LEC	Ligand-exchange Chromatography
LIF	Laser-induced Fluorescence
Man	D-Mannose
ManA	D-Mannuronic Acid
Man 6-P	Mannose 6-Phosphate
MS	Mass Spectrometry
MurNAc	Muramic Acid
NAD^+	Nicotinamide Adenine Dinucleotide
NADH	Reduced Nicotinamide Adenine Dinucleotide
$NADP^+$	Nicotinamide Adenine Dinucleotide Phosphate
NADPH	Reduced Nicotinamide Adenine Dinucleotide Phosphate
Neu5-Ac	*N*-Acetylneuraminic Acid
PA	Polyacrylamide
PAD	Pulsed Amperometric Detection
PAGE	Polyacrylamide Gel Electrophoresis
PC	Paper Chromatography
PE	Paper Electrophoresis
PGI	Phosphoglucoisomerase
PITC	Phenyl Isothiocyanate
PMAA	Partially Methylated Alditol Acetate
PMI	Phosphomannoisomerase
PMP	1-Phenyl-3-methyl-5-pyrazolone
Purpald	4-Amino-3-hydrazino-5-mercapto-1,2,4-triazole
Rha	L-Rhamnose
Rib	D-Ribose
RPLC	Reversed-phase Liquid Chromatography
TDP-Rha	Thymidine Diphosphate L-Rhamnose
TLC	Thin-layer Chromatography
TRSE	5-Carboxymethylrhodamine Succinimidyl Ester
UDP-Glc	Uridine 5′-(α-D-Glucopyranosyl Diphosphate)
UTP	Uridine Triphosphate
UV	Ultraviolet
Xyl	D-Xylose
2-AP	2-Aminopyridine

The isolation and analysis of proteoglycans (PGs) and the acidic polysaccharide glycosaminoglycan (GAG) chains attached to them is an area of increasing importance. PGs are a structurally diverse group of complex macromolecules comprising a core protein, varying in size from 11 to 400 kDa, to which are attached one or more GAG chains of the same or a different type. These chains carry a negative charge derived mainly from sulfate groups and are composed of a repeating disaccharide, a hexosamine and either a hexuronic acid or, in keratan sulfate (KS), galactose.

1 INTRODUCTION

The isolation and analysis of PGs and the acidic polysaccharide GAG chain attached to them is an area of increasing importance. PGs are a structurally diverse group of complex macromolecules comprising a core protein, varying in size from 11 kDa[1] to 400 kDa,[2] to which are attached one or more GAG chains of the same or a different type (Table 1). These chains carry a negative charge derived mainly from sulfate groups and are composed of a repeating disaccharide, a hexosamine and either a hexuronic acid or, in KS, galactose.

2 PROTEOGLYCANS

PGs are found on mammalian cell surfaces and in extracellular matrixes,[3] in plants,[4] and in invertebrates[5] (Table 1). Several large PGs share features and properties with the prototypical member of the class, the large aggregating PG aggrecan (Table 1). Aggrecan monomers comprise a protein core of ca. 250 kDa to which are attached ca. 100 CS and ca. 50 KS chains. Up to 100 of these monomers form large aggregates of up to 5×10^6 kDa through interaction with hyaluronate (HA). Small leucine-rich PGs[3] have a protein core comprising leucine-rich tandem repeats of ca. 24 amino acids

Table 1 Structures and properties of a selection of PGs. (This table is not designed to be a comprehensive list of PGs)

PG	Core (kDa)	Location	Glycosylation (number)	Notes
Aggrecan	220	Cartilage	CS ca. 100, KS ca. 50	
Versican	265	Fibroblasts	CS	
Neurocan	150	Brain	CS	
Fibromodulin	59	Cartilage	KS up to 4, N-linked oligos balance to 4	Inhibits collagen fibril formation
Decorin		Cartilage, skin, tendon	CS 1, N-linked oligos 3?	Inhibits collagen fibril formation. Binds to TGF-β
Biglycan		Cartilage, skin, tendon	CS 3, N-linked oligos 3	
Lumican (corneal)		Cornea	KS 1	
Lumican (arterial)		Artery	Lactosaminoglycan	Normal noncorneal glycosylation
Prelp	58	Cartilage	KS ? 3?	Binds to chondrocytes[137]
Keratocan		Cornea	KS 3	
Chondroadherin		Cartilage		Binds to chondrocytes[137]
Perlecan	30–400	Basement membrane	HS	
Serglycin	17–19	Hemopoietic cell vesicles	Heparin, CS, DS, HS	
Syndecan	31	Many cell types	CS, HS	
Betaglycan	110	Many cell types	CS, HS	
Synaptoglycan	82–83	Synaptic vesicles	KS	
CD44	90	Many cell types	CS, KS	
Glypican	62	Fibroblasts, brain	HS	
Cerebroglycan	58–59	Developing nervous system	CS 1	

CS, chondroitin sulfate; DS, dermatan sulfate; HS, heparan sulfate; TGF-β, transforming growth factor beta.

repeated up to 12 times, a motif which may be involved in binding to other macromolecules.[6]

Fibromodulin is glycosylated by four short N-linked KS chains[7–10] attached within, or close to, the leucine-rich repeat region. This is in contrast to both decorin and biglycan in which the CS/DS chains are located close to the N-terminus. There is evidence that fibromodulin, along with decorin, has a role in the maintenance of the collagen fibrils which make up the extracellular matrix of cartilage. The core protein of fibromodulin binds to collagen monomers[11,12] and the KS chains apparently control fibril diameter and interfibrillar spacing.[13]

2.1 Is my Protein Glycosylated?

If it is suspected that an isolated macromolecule is a PG, the presence of glycosylation should be confirmed; later, the nature of the carbohydrate may be investigated. This is most easily done using a commercial carbohydrate detection kit, which relies upon the oxidation of adjacent hydroxyl groups in carbohydrates to aldehydes. The aldehydes react with either digoxigenin (Roche Molecular Biochemicals, http://193.197.95.199 Glycan Detection Kit) or biotin hydrazide (Glyko, http://www.glyko.com) and are detected using peroxidase or alkaline phosphatase conjugated to an antibody or to streptavidin, respectively.

2.2 Inhibition of Glycosylation

An unglycosylated PG core protein may be expressed in culture if a glycosylation inhibitor is present. Inhibitors include deoxynojirimycin and swainsonine, which block the processing of high-mannose oligosaccharides to complex oligosaccharides; however, swainsonine does not affect hybrid chains. In contrast, tunicamycin inhibits the formation of dolichol pyrophosphate *N*-acetyl-glucosamine. All of these inhibitors will inhibit N- but not O-linked chain synthesis.

2.3 Metabolic Labeling During Synthesis

A radiolabel may be introduced by addition of ^{35}S- or ^{3}H-containing substrates to the growth media during culture. Radiolabeled [^{35}S]sulfate is incorporated into GAGs to examine sulfation, [^{3}H]glucosamine will label most GAGs, [^{3}H]glucose is converted to many sugar precursors and becomes incorporated into most carbohydrates, while [^{3}H]mannose will label only N-linked chains. If [^{3}H]leucine is used then the protein core, along with all other proteins, will be labeled. Radiolabeling can provide a measure of synthesis and sulfation under modified growth conditions, as only newly synthesized molecules are labeled, while pulse chase experiments can provide information on turnover.

2.4 Extraction

A tissue or cell layer can contain many different PGs and their structure and extractability may differ widely, so no single protocol is appropriate for the extraction, isolation and analysis of all PGs. In a tissue such as cartilage they may be trapped by the collagen meshwork

or bound by noncovalent interactions to other molecules, while brain PGs are very readily extracted. Cell surface PGs may be attached via a hydrophobic domain or phosphatidylinositol anchor while other PGs are found intracellularly.

Unless an extraction protocol has already been established, both 4 M guanidine hydrochloride (GuHCl) and 4% 3-([3-cholamidopropyl]dimethylammonio)-1-propanesulfonate (CHAPS) should be included in an extraction buffer. The zwitterionic detergent CHAPS is easier to remove subsequently than the micelle-forming Triton™ X-100, and its inclusion when extracting cells reduces artifactual hydrophobic interactions induced by GuHCl.[14]

Extraction of cartilage PGs[15] is performed for 24 h at 4 °C into 7–10 mL g^{-1} of tissue with 4 M GuHCl, 50 mM sodium acetate (pH 6.8), 100 mM 6-aminohexanoic acid, 20 mM benzamidine hydrochloride, 0.5 mM phenylmethylsulfonyl fluoride, 10 mM ethylenediamine tetraacetic acid (EDTA) and 5 mM *N*-ethylmaleimide, to prevent degradation. Extraction efficiency is increased if the tissue pieces are small; ideally 20-μm cryostat sections or chopped or powdered tissue should be used. Powdered tissue is obtained by pulverizing the tissue after freezing in liquid nitrogen, although there is some evidence of damage to PGs using this method.[16] Connective tissues contain insoluble collagen and inextractable PGs and GAGs which are only accessed by digestion of the collagen network or release of the GAGs (see section 3.1).

2.5 Isolation

Methods used in the separation of PGs from each other, and from nonPGs, often focus on the negative charge generated by the attached GAGs. However, other properties can also be utilized; PGs have larger hydrodynamic volumes and buoyant densities than the size of their protein cores would suggest, and cell surface PGs often have a hydrophobic transmembrane region.

2.5.1 Centrifugal Techniques

The high buoyant density of PGs allows the almost pure single-step isolation of large PGs in a self-forming CsCl density gradient. Smaller PGs also benefit, becoming separated from larger PGs and smaller proteins. If >0.5 M GuHCl is present the gradient is dissociative and may thus be used to isolate PGs from other extracted macromolecules with which they interact; at lower GuHCl concentrations the gradient is associative. CsCl is added to an extract to achieve a density of 1.6 g mL^{-1} using $X = V(1.347\rho - 0.038M - 1.347)$, where X = weight of CsCl in grams, V = final volume, M = molarity of GuHCl, and ρ = density. The density should be confirmed by weighing a 1-mL sample before ultracentrifugation at 88 500 g_{av} for 48 h at 12 °C. If cell surface PGs are being isolated, or the PG is believed to be hydrophobic, 0.5% CHAPS should also be included.[15]

Following centrifugation the gradient can be fractionated by sucking the solution out from the bottom of the tube with a peristaltic pump attached to a stiff, hollow tube, or by piercing the bottom of the tube and allowing the gradient to drip out. The fractions should be assayed for density and for GAGs or PGs of interest, then pooled appropriately. Large PGs such as aggrecan are found at the bottom (>ca. 1.5 g mL^{-1}, A1), while small PGs such as fibromodulin, decorin and biglycan are present towards the top (<ca. 1.45 g mL^{-1}, A3/A4).[17]

2.5.2 Chromatographic Analysis

Before their first use for chromatography of PGs or GAGs it is necessary to condition all column media with CS and BSA (bovine serum albumin) (both ca. 1 mg mL^{-1}) to prevent nonspecific binding of the samples.

2.5.2.1 Ion-exchange Chromatography The negative charge of the GAGs attached to PGs brings about their binding to anion-exchange matrices and their separation from both uncharged macromolecules and from each other in an appropriate elution gradient. The method is not sensitive to sample volume or to chaotropic agents, and so is often used as the first chromatographic step during purification. Nonspecific adsorption of nonPGs and less than 100% recovery of bound PGs may be minimized by careful attention to the capacity of the matrix and column size, or the amount of resin when used in batch mode, together with a low, nonzero, salt concentration in the starting buffer.

For example fibromodulin is isolated in an almost pure form by ion-exchange chromatography (IEC) following CsCl density gradient centrifugation, where it bands at A3/A4. It is eluted from a Mono-Q® HR 10/10 column with a linear gradient of 0.15–1 M NaCl in 6 M urea/50 mM TRIS (tris(hydroxymethyl)aminomethane) · HCl, pH 7.3, and is found in the fractions between 0.4 and 0.8 M NaCl. The related small PGs decorin and biglycan elute at higher salt concentrations (Figure 1). The eluent is monitored online at 280 nm and fractions are assayed for GAG and PGs. Nucleic acids, however, which are common in cell extracts, may bind to anion-exchange resins, and the 1,9-dimethylmethylene blue (DMB) assay (see section 3.3.5) which will respond to GAGs but not nucleic acids should be used to reliably estimate GAG abundance.

Figure 1 IEC on a Mono-Q® column of A3/A4 density gradient fraction. An aliquot of an A3/4 fraction recovered from a CsCl gradient of a GuHCl extract of bovine articular cartilage (ca. 20 mg) was loaded onto a Mono-Q® 10/10 column. The bound material was eluted in a 0.15–1 M NaCl gradient in 6 M urea, 50 mM TRIS · HCl at pH 7.5. The elution positions of fibromodulin, which elutes as five distinct functions (Q1–Q5), decorin and biglycan are shown. ——, optical density (OD) at 280 nm; - - - - -, fibromodulin enzyme-linked immunosorbent assay (ELISA).

2.5.2.2 Size-exclusion Chromatography Size-exclusion chromatography (SEC) is widely used for the isolation and analysis of molecules of all sizes. Because of the large apparent hydrodynamic volume of PGs, and GAGs, quoted ranges for globular proteins may not be a good measure for the appropriateness of a column. Chromatography will usually be performed using a salt-containing eluent to inhibit interactions with the resin. One exception is Bio-Gel® P2, which may be used at 50 °C in distilled water (dH_2O) for desalting. A volatile salt such as ammonium acetate may obviate the need to desalt before subsequent analysis, but during lyophilization significant drops in the pH can occur which have been found to cause the loss of labile groups such as *N*-acetylneuraminic acid (NeuAc). For large PGs, such as aggrecan, CL-2B resin allows isolation of the aggregated PG under associative conditions and isolation of the monomers under dissociative conditions. Tryptic digest products of aggrecan can be isolated using a CL-6B column while smaller PGs may be isolated using CL-6B, Superose 6, S-300 or HW-55 s. The final choice of medium will depend upon the structure of the PG under investigation and the nature of the material it is being separated from.

2.5.2.3 Hydrophobic Interaction Chromatography Hydrophobic interaction chromatography (HIC) relies upon the hydrophobicity of a molecule and separation is performed in a gradient of decreasing salt or increasing chaotropic agent or CHAPS. In common with IEC, it is not sensitive to loading volume but is not able to support the high sample loading of IEC. Factors including temperature and pH affect elution, with increasing temperature retarding elution.

Decorin and biglycan, which co-elute from a Mono-Q® column (Figure 1), are separated on a 300-mL Octyl-Sepharose® HIC[18] column. The PG mixture (40 mg) should be applied in 4 M or 2 M GuHCl and eluted with a gradient of 0–1% CHAPS or 2–6 M GuHCl respectively.

2.5.2.4 Reversed-phase Chromatography Reversed-phase chromatography (RPC) is not widely used in the isolation of PGs because of its low capacity and the fact that the nonpolar stationary phase may denature a PG. However, the high resolution attainable makes it appropriate for confirming purity[7] as elution is dictated almost exclusively by the peptide. It is also used in the separation of PG fragments generated by tryptic

digestion for the isolation of a GAG attached to a specific glycosylation site.[10]

2.5.3 *Immunopurification*

If an antibody to the PG or the attached GAG chains is available it may be conjugated to a medium such as Dyna-Beads™ or to a column support matrix that allows isolation by immunopurification.

2.6 Analysis of Intact Proteoglycan

2.6.1 *Electrophoresis of Proteoglycan or Protein Core*

The resolution of PGs by SDS/PAGE (sodium dodecyl sulfate/polyacrylamide gel electrophoresis) is often poor because of the polydispersity of chain sulfation and size. Small PGs have been successfully separated using electrophoresis on 8–20% gradient gels and although large PGs will not enter a conventional gel they may be electrophoretically separated on 1.2% polyacrylamide–0.6% agarose.[17,19] For this procedure an acrylamide plug is made by mixing 10 mL of 30% acrylamide (comprising 29.1% acrylamide–0.9% bisacrylamide) with 18.47 mL of distilled water, 30 µL of *N*,*N*,*N*′,*N*′-tetramethylethylenediamine and 1.5 mL of fresh 3% ammonium persulfate. A ca. 3-cm plug is poured and then overlaid with dH_2O saturated butanol. Then 0.24 g of agarose is added to 22.5 mL of solution A (40 mM TRIS · acetate–1 mM sodium sulfate, pH 6.8), and brought to the boil. Acrylamide (0.456 g) and 0.024 g of bisacrylamide are dissolved in 9.7 mL of solution A, then 4.8 mL of fresh 6.4% β-dimethylamino-propionitrile is added and the mixture is warmed. The plug is blotted dry and heated to 60 °C. When the boiled agarose solution has cooled to 50 °C, 3 mL of 3% ammonium persulfate is added to the acrylamide solution, and mixed and added to the agarose. The mixture is poured onto the plug, and a well former is inserted and overlaid with dH_2O saturated butanol.

Aggrecan monomers (5 µL at 1 mg mL^{-1}) in 25% solution A containing 20% sucrose and 0.001% bromophenol blue are then applied to each well. Electrophoresis is carried out in 25% solution A at 60 V until the dye enters the gel, then at 120 V; the PGs should not approach the supporting plug too closely. Following electrophoresis the gel is stained in 200 mg toluidine blue–100 mL 0.1 M acetic acid and destained in 3% acetic acid. Radiolabeled PGs are visualized by fluorography of a fixed gel (15 mM sodium acetate in ethanol containing 0.4% PPO (2,5-diphenyloxazole)). The dH_2O washed and dried gel is sealed in a light-tight box in contact with pre-flashed X-ray film at −70 °C. Exposure time depends upon activity, but as a general guide 1000 dpm (disintegrations per minute) ^{35}S requires ca. 48 h of exposure.

2.6.2 *Enzyme-linked Immunosorbent Assay*

ELISA is a well-established technique for the detection and quantification of structures for which an antibody is available. There are two methods, namely direct and inhibition. The former is appropriate for rapid determinations of the presence of a PG, and the latter more complex method is used for quantitative analyses. In a direct ELISA a sample is coated onto the well of a microtiter plate in 20 mM sodium carbonate at pH 9.6, and after washing in phosphate-buffered saline (PBS) with 0.5% Tween 20 to remove unbound material (performed after each step) an antibody to the antigen of interest is added to each well. This is followed after 1 h by an enzyme-conjugated second antibody which binds to the first. A substrate for the enzyme which generates a colored product is added, and after a fixed time the abundance of this product is estimated by measuring its absorbance, which is proportional to the concentration of the original antigen of interest. In an inhibition ELISA the sample and primary antibody are pre-incubated and then transferred to a microtiter plate, the wells of which are coated in a standard containing an example of the antigen being examined. Excess primary antibody binds to this coated material and may be estimated as described previously.

2.6.3 *Nuclear Magnetic Resonance and Mass Spectroscopy*

Nuclear magnetic resonance (NMR) is a powerful, nondestructive technique, allowing the analysis of an intact PG and its recovery for further analysis. Because a PG is large, signals deriving from the amino acid backbone will be complex, but if aromatic residues are present they will have signals in the otherwise clear area at ca. 7–8 ppm. It can be difficult to get GAG-related information from spectra acquired with an intact PG, although there are some key regions from which information can be derived that are generally free of protein signals. Samples need not be completely pure, although it is typically necessary to have ca. 0.5–1 mg of sample. However, complete ^{1}H characterization of an octasaccharide has been reported where less than 125 µg of sample was available.[20]

Mass spectroscopy (MS) techniques allow the accurate estimation of the mass of an intact PG as the heterogeneity of peaks reflects the heterogeneity of post-translational processing, including glycosylation. Clearly the estimation of mass before and after removal of any GAG chains will allow a determination of the mass of GAGs removed, providing what is potentially a very powerful method for the determination of the nature and size of a GAG along with its enzymatic susceptibility.

2.7 Removal of Glycosaminoglycans to Yield an Intact Protein Core

Peptide-*N*4-(acetyl-glucosaminyl)-asparagine amidase (EC 3.5.1.52, PNGase F) will release many N-linked KS chains by breaking the GlcNAc–Asn bond and completely removing the GAG chain leaving both it and the protein core intact, except for the deamination of Asn to aspartic acid. It acts upon Asn-linked high mannose, hybrid and complex oligosaccharides, but will not act upon chains which contain fucose α(1,3)-linked to the terminal GlcNAc, although α(1,6)-linked fucose has no effect; the Asn must have at least one amino acid residue on both sides (Figure 2).

The PG should be heat denatured with a minimum volume of 1% SDS (sodium dodecyl sulfate) and 1 M β-mercaptoethanol by heating at 100 °C for 5 min. Following cooling Triton™ X-100 is added at 5× excess relative to SDS. PNGase F is then added at 1 U per 20 mg of PG and allowed to digest for 12 h at 37 °C. This can be extended to 24 h if the PG is not denatured or the effect of SDS is not reduced by Triton™. The enzyme is extremely robust and will remain active in the digestion buffer for over 24 h.

There are other endoglycosidases that act upon N-linked chains, although none release the intact chain. Endoglycosidase A (PNGase A, EC 3.5.1.52) cleaves chains with fucose α(1,3)-linked to the terminal GlcNAc; chains upon which PNGase F will not act. However cleavage occurs between the two linkage region GlcNAc residues leaving a single GlcNAc attached to the protein core. There are several endoglycosidase Fs (EC 3.2.1.96) that have significantly different substrate specificities, so it is crucial to confirm the specificity of the enzyme purchased. Each endoglycosidase F cleaves between the two GlcNAc residues of the linkage region: F_1 cleaves hybrid and oligomannose (but not complex) oligosaccharides; F_2 cleaves high mannose and biantennary complex oligosaccharides, showing a significant preference for the complex type, and no activity towards hybrid type or tri- and tetraantennary oligosaccharides; F_3 cleaves only bi- and triantennary complex type oligosaccharides, showing no activity towards hybrid or high mannose type.

No single enzyme will remove all O-linked GAGs, and chains must be depolymerized to leave the linkage disaccharide Galβ(1-3)GalNAc, which may be removed using *endo-O*-glycosidase (*O*-glycopeptide *endo*-D-galactosyl-*N*-acetyl-α-galactosaminohydrolase, EC 3.2.1.97) only following the removal of the rest of the chain (Figure 2).

CS/DS chains may be depolymerized by chondroitin ABC lyase (EC 4.2.2.4) (Figure 3), and the terminal

Figure 2 Structural models of KS and specificity of chemical and enzymatic methods for depolymerization. Structural models for corneal and skeletal KS are shown; note the absence of α(2-6)-linked NeuAc and fucose in both O- and N-linked KSs from nonarticular cartilage. The specificity of methods of depolymerizing KS are also shown. For the repeat region 1 = *endo*-β-galactosidase, 2 = keratanase, 3 = keratanase II and 4 = hydrazinolysis/nitrous acid. ✓ = can cleave, × = cannot cleave, ? = unknown.

Figure 3 Specificity of CS degrading procedures. The specificity of enzymatic and chemical methods of depolymerizing CS are shown. A and B refer to enzyme action on intact chains while C and D are isolated tetrasaccharides; 1 = chondroitin ABC endo/exo lyase; 2 = chondroitin; a = ACI; b = ACII; c = ACIII (if (a), (b) and (c) are not shown separately all can cleave) and 3 = chondroitin C lyase. Chondroitin B lyase acts solely upon DS. ✓ = can cleave, × = cannot cleave, ? = unknown.

ΔUA that the enzyme generates can be removed using 35 mM mercuric acetate, pH 5, at ambient temperature for 30 min,[21] excess Hg being removed by cation-exchange chromatography. The Gal residues may then be cleaved by β-galactosidase (EC 3.2.1.23), which acts only upon a terminal residue. The remaining xylose requires a xylosidase for its cleavage. Such enzymes have been isolated and used to remove the intact chain, but are not commercially available at present; their widespread availability will represent a significant advance in the isolation of O-linked GAG chains.

Heparin/HS may be depolymerized and the remaining linkage region removed as described for CS/DS, but there is no single enzyme that will depolymerize all chains leaving the linkage region (see section 7.2).

Enzymatic methods are specific but they may not always be appropriate, e.g. if there is a spectrum of GAGs of known or unknown type, or if their structure is such that enzymatic deglycosylation fails. In contrast chemical deglycosylation methods have a broad specificity and may be used to deglycosylate a PG with GAG chains of an unknown type. Techniques used include anhydrous HF at 23 °C for 3 h, which cleaves neutral and acidic sugars along with *O*-glycosidic links but not *N*-glycosidic links,[22] 70% HF in pyridine with 10% anisole at ambient temperature for 8 h,[23] and Smith degradation[23] and methanolysis for 17 h at 80 °C.[24] Note however that there are reports of variable removal of carbohydrates and solubility problems following deglycosylation by HF methods.[24] Gerken et al.,[25] in a modification of the method of Edge et al.,[26] used trifluoromethanesulfonic acid (TFMS). Anisole and TFMS are mixed 1 : 2 in a glass tube, cooled in a dry ice–ethanol slurry and 1 mL was added to 5–10 mg of dry sample. Nitrogen was bubbled through the solution for 30 s followed by stirring at 0 °C for 6 h after which 1 volume of cold anhydrous diethyl ether was added and the mixture slowly added to 12.5 mL of a frozen slush of 60% pyridine. The mixture was allowed to warm to ambient temperature and extracted with ether, the aqueous phase being recovered. Subsequent periodate oxidation followed by an alkaline dialysis was required to remove the linkage residue remaining attached to the core protein. This method has been used to deglycosylate O- and N-linked KS;[27] no studies have examined its action on CS/DS and heparin/HS, although it would be expected to deglycosylate these GAGs.

The removal of a GAG chain may modify the structure or properties of the intact protein core by exposure of previously masked regions, or through disruption of intramolecular interactions.

2.8 Amino Acid Analysis

Amino acid analysis can be very important in the identification of a PG. A pure sample, ca. 20–100 μg, should be subjected to vapor phase acid hydrolysis with

Figure 4 Amino acid analysis of fibromodulin. An aliquot (1 μL) of a PITC derivatized hydrolysate was applied to a Spherisorb® ODS (3 μm 150 × 4.6 mm) column and the amino acids were eluted at 1.5 mL min^{-1} in 0–100% buffer B (50% acetonitrile–50% 24 mM sodium phosphate, pH 6.4). Buffer A is 12 mM sodium phosphate, pH 6.4.

6 M HCl at 105 °C for 24 h, followed by lyophilization and a redrying step in 40% ethanol–20% triethylamine–40% water. Under basic conditions amino groups are coupled to phenylisothiocyanate (PITC) in 70% ethanol–19% water–10% triethylamine–1% PITC at 25 °C for 20 min. Free PITC will poison the column (Spherisorb® ODS 2–3 μm 150 × 4.6 mm) and must be removed by lyophilization prior to chromatography. Labeled amino acids are unstable at ambient temperature and should be stored at −80 °C. Aliquots are resuspended in a minimum volume of buffer A (12 mM sodium phosphate, pH 6.4) and chromatographed at 1.5 mL min^{-1} with a gradient of 0–100% buffer B (50% acetonitrile–50% 24 mM sodium phosphate, pH 6.4) with detection by absorbance at 245 nm (Figure 4).

A control protein should be examined to estimate losses, and the column calibrated with commercial amino acids labeled with PITC. When the composition has been determined, searching the Swiss-Prot database (http://www.expasy.ch/tools/aacomp/) for entries with the appropriate composition may yield the identity of an unknown. If the sequence is available there are tools for the analysis of this data (http://www.expasy.ch/tools/). The NetOGlyc site (http://www.cbs.dtu.dk/services/NetOGlyc/) predicts *O*-glycosylation sites in mammalian PGs where the sequence is known.

2.9 Where are the Chains Attached?

The primary amino acid requirements for glycosylation are well established, but not all potential sites are necessarily glycosylated. Experimentally, a blank cycle at a potential glycosylation site during amino acid sequencing points to the presence of a glycosubstitution. An elegant approach was taken by Plaas et al.[10] who used trypsin to digest a PG and isolated the peptido-KS chains by IEC. Then they used RPC to separate these into pools with the same amino acid sequence. The GAG chains of each pool were characterized and the peptide sequenced, identifying its position in the parent PG and thus revealing the nature of the glycosylation at a specific site.

3 ACIDIC POLYSACCHARIDES

In mammalian tissues there are four GAGs: HA, KS, CS/DS and HS/heparin (Figure 5) which, with the exception of HA, are synthesized attached to PGs and comprise a chain cap, a linkage region which connects the chain to the protein core, and an intervening repeat region. The repeat regions consist of a repeating disaccharide comprising a hexosamine and either a hexuronic acid or, in KS, galactose (Figure 5). Each residue, apart from those of HA which exist as an invariant linear sequence without sulfation or other modifications, may be sulfated, in some cases by more than one sulfate group, rendering GAGs highly negatively charged.

Figure 5 GAG disaccharide structure. The basic disaccharide structures of each GAG are shown. Note the epimerization of C5 in CS/DS and in HS/heparin.

The detailed microstructure of GAGs is crucial to their function, e.g. 4-sulfated GalNAc in CS has a role in the adherence of the malaria parasite to human placenta,[28,29] iduronic acid (IdoA) is required for binding DS to the growth promoter spermine[30] and *N*- and 2-*O*-sulfate groups on the HS of syndecan-1 are important in collagen binding.[31] Other important GAG structures include that of the antithrombin III binding site in heparin,[32] the heparin cofactor II binding site in DS[33] and the bFGF binding sequences in HS.[34]

3.1 Release of Intact Carbohydrates from the Protein Core

Enzymatic procedures for the removal of N-linked GAGs yield the intact chain (see section 2.7), but as discussed previously no such method exists for O-linked chains, and alternative approaches are required.

3.1.1 β-Elimination

Chains that are O-linked are alkali labile and incubation in 0.1 M NaOH at 45 °C[35] or 0.05 M LiOH at 4 °C for 24 h[36] will release them. The former method

requires 1 M $NaBH_4$ to reduce the released chains and prevent degradation due to the high pH, while the latter allows the isolation of intact chains terminated with a reducing sugar. This residue has been used to fluorescently label the CS linkage region for high pH anion-exchange chromatography (HPAEC) analysis[37] and sequencing.[38] Although not readily alkali-labile, N-linked KS chains may be liberated by strongly alkaline conditions such as 1 M NaOH–1 M $NaBH_4$ at 100 °C for 4–6 h.[39]

3.1.2 Hydrazinolysis

Chains with either N- or O-linkages may be released unreduced by hydrazinolysis.[40] Lyophilized samples (5–10 mg mL^{-1}) are resuspended in anhydrous hydrazine and heated to 60 °C for 5 h to release O-linked chains and to 95 °C for 5 h to release N- and O-linked chains. Excess hydrazine, made safe by the addition of one volume of dH_2O, is removed by evaporation under vacuum at 25 °C. Primary amino groups are re-*N*-acetylated by an excess of 0.5 M acetic anhydride in saturated $NaHCO_3$ at 4 °C for 20 min and then at ambient temperature for 30 min. The procedure may also be performed by automated hydrazinolysis, which is reported to require a minimum of ca. 50 μg of sample for efficient release and recovery.[41]

3.1.3 Digestion/Destruction of Protein

If the amino acid on the protein core to which the GAG chain is attached is to be retained, or if complete release is not essential, the protein core may be extensively digested by a broad specificity protease such as papain. It is used at a level of 1 U per 100 mg of tissue in 0.1 M sodium acetate at pH 6.8 with 2.4 mM EDTA and 10 mM cystein HCl, added just prior to digestion, at 60 °C overnight. The mixture is boiled for 30 min or iodoacetamide is added to 10 mM to inactivate. The elevated temperature at which papain digestion is performed gives it a significant advantage over the use of other proteases as unwanted enzymatic activity will be prevented. The remaining peptide may then be used to conjugate biotin, or any other label or probe, via the amino terminus.

3.2 Isolation of Glycosaminoglycans from Other Glycosaminoglycan and Nonglycosaminoglycan Contaminants

GAGs which have been released from their protein core need to be separated from peptides and may need to be fractionated if more than one GAG is present. The choice of method depends upon the amount of GAG expected, what it is being separated from, and the required purity.

3.2.1 Precipitation

The GAGs have different solubility in organic solvents, and are precipitated by the careful addition of ethanol while stirring to the following total number of volumes: heparin 0.1–0.4, DS 0.5–0.8, CS 2, KS 3. After 15 h at 4 °C the GAGs appear as a white precipitate or a sticky mass which is easily recovered. Higher purity will be achieved by precipitating all GAGs, resuspending them in an appropriate volume of 0.1 M sodium acetate, and performing another series of ethanol precipitations. Volpi[42] used the following volumes of propanol for precipitation: heparin 0.3–0.4 volumes, DS 0.5–0.6 volumes and CS > 0.8 volumes.

Cetyl pyridinium chloride (CPC) can also precipitate GAGs. Following papain digestion, 1% CPC is added and the mixture is centrifuged for 1 h, then the pellet is washed with NaOAc saturated ethanol.

3.2.2 Chromatographic Separation Methods

GAGs may be separated from nonGAG material by IEC, essentially as discussed for intact PGs. KS chains have been successfully isolated from nonGAGs and from contaminating CS using Mono-Q® or Q-Sepharose® IEC in a gradient of 2–500 mM $LiClO_4$–10 mM piperazine. Many IEC methods suffer from less than 100% recovery and use of a column with appropriate dimensions is important. Other strategies appropriate for the isolation of labeled GAGs involve the use of unlabeled carrier. Alternatively, intact GAG chains can be separated from smaller oligosaccharides by SEC.

3.2.3 Dialysis

Dialysis and centrifugal partition utilize a membrane through which small molecules such as salt and depolymerized oligosaccharides will pass, but larger molecules will not. Dialysis is appropriate if the GAG is abundant and in a large volume. However, if the amount of GAG and the volume it is in are small, then centrifugal partition will allow its separation from salt and smaller oligosaccharides, and permit it to be recovered in a small volume. The use of a high-quality dialysis membrane with a closely defined pore size is crucial. There are many tricks for the dialysis of small volumes. These include placing a sample in a centrifuge tube with a hole in the cap covered with dialysis tubing; the tube is inverted and the sample dialyzed before being recovered in the tube by gentle centrifugation. The large volume of a dialyzate makes its analysis impractical, while centrifugal partition allows examination of both retentate and filtrate to confirm that there is neither loss of desired material nor retention of undesired material.

3.3 Estimation of Glycosaminoglycan Abundance

GAG abundance may be estimated, following isolation or while still attached to a PG, by an assay relying upon the interaction of the GAGs and a dye. The GAG–dye complex may be precipitated and the amount of dye present estimated, or a change in absorbance of the complex quantified. It is important to note that with the exception of the method of Bjornson[43] the response from each GAG is different. Following depolymerization GAGs show no response and the abundance of each may be determined in sequence by the reduction in the response following digestion with an appropriate enzyme. The presence of common eluents such as GuHCl will modify the response, but if appropriate controls are used responses will remain linear.

3.3.1 Alcian Blue Solution Method[44]

In this method 100 μL of sample is mixed with 1.2 mL of fresh 1.4 mg mL^{-1} alcian blue in 0.5 M sodium acetate and the absorbance is determined at 480 nm after 10 min. This assay is not very sensitive and suffers from interference from high levels of salt, but it is very rapid and is linear from 10 to 100 μg mL^{-1}.

3.3.2 Alcian Blue Precipitation Assay I[45]

This assay involves the precipitation of an alcian blue–GAG complex and subsequent dissociation of the dye using surfactants. It is possible to use $MgCl_2$ in a critical electrolyte concentration technique to prevent the binding of certain GAGs,[46] although at low concentrations all GAGs will bind.

To 1 mL of freshly prepared centrifuged dye solution (0.05% alcian blue in 50 mM sodium acetate–50 mM $MgCl_2$, pH 5.8) is added 20 μL of sample (1–10 μg). After 2 h at ambient temperature the mixture is centrifuged at 2000 g for 10 min, then the pellet is washed in 2 mL of ethanol and resuspended in 1 mL of 10% SDS in 50 mM sodium acetate (pH 5.8) and the absorbance is measured at 620 nm.
